THE FEEDING ECOLOGY AND BEHAVIOUR OF INSHORE FISHES

by<br>Pahriye Mina Kislalioglu B.Sc. (Univ. London).

Thesis submitted for the degree of Doctor of Philosophy
in the
University of Stirling.

November 1975

## ACKNOWLLDGEMENTS

I wish to express my sincere gratitude to my supervisor Dr. R.N. Gibson for his continuous encouragement, advice and constructive critisism throughout the present atudy. My thanks are also due to Dr. J.H.S. Blaxter for reading the manuscript and his helpful suggestions. I would like to thank the Director Mr. R.I. Currie and the staff of Dunstaffnage Laboratory where this work was carried out and in particular to Dr. J. Gage for his help in identification of amphipods.

I am grateful to Roy Summers for the photographic work, to I. Drumond for his help in collecting the samples. My special thanks are to Mrs Elsie MacDougall for typing the manuscript. This vork was supported by a Turkish Government grant.

## ABSTRACT

The food and feeding relationships of 21 species of inshore Pish from Loch Etive were examined over a 13 month period from October 1971 to October 1972. Some aspects of the feeding behaviour of two species Spinachia spinachia and Pholis gunnellus were investigated experimentally under laboratory conditions.

With the exception of three species which were zooplankton feeders, the majority of the fish examined were benthos feeders. Amphipods were the most heavily preyed upon benthic food group.

Most fishes depended on relatively few prey types as their major food, the number of principal food types vere commonly between 2 to 5 and there vas often an overlap between the main food types of both related and unrelated fish species. The majority of the fishes utilized aimilar sources of food, but the proportions of the most commonly occurring food types eaten by different fish species were significantly different.

The types of main food groups in the diet of individual species usually did not alter throughout the year, but their importance in relation to one another frequently changed. The quantity of food in most fishes diets, however, exhibite: a marked
seasonal variation. In the aiet of some fishes there was evidence for a cleazly defined size-related feeding heterogeneity, in others prey size selection was less marked.

The effects of some visual cues utilised in pre; selcction by S. spinachia and $P$. gunnellus were tested. S. Sp pachia showed a marked prey size selection under experimentbl conditions -hen the catchability of prey was strictly control d. Selectivity was found to be related to aunger level. There was an optimal prey size for waich the fish showed greatest selecion. This optimal prey size was much smaller than the maximim prey size the fishes could swallow, but it coincided with t. a critical prey size, defined as the size et which the prey hand rg time began to increase drastically. Fs, gunnellus exhibited less clear prey size selection pattern and no optimal prey size was found. . The fish took prey of a wide size range, showing prefertace for the larger prey within the preferred size range. Both dishes showed a marked preference for moving prey, selection for $\mathfrak{L}$ wement overruling the selection for size. P. gunnellus hid a nerrower preferredparange of prey then S. spinachia.

Purther experiments with Spinachia in which $t^{2}$ : irfluence of shape and shade were tested, suggested that he order of
importance of the visual stimuli presented by a prey organism was: movement $>$ size $>$ colour $>$ shape.

## GENERAL INTRODUCTION

Fishes inhabiting shallow coastal waters are often present in considerable numbers and undoubtedly play a major role in the economy of intertidal areas, especially as predators. In general, however, the feeding habits of most inshore fish, particularly those which have no commercial value, have not been investigated as intensively as the comercially exploited species.

Most research on the food of fishes has been focused on single species, and other members of the same community are considered chiefly as predators or as potential food. Iet it is generally realised that interspecific competition for food may be an strong as intraspecific competition in its limiting effects on reproduction and growth etc. Nikolsky (1945) has commented that only by the comparative study of the feeding habits of different species can an understanding of the qualitative and quantitative connections between fishes and their food organisms be gained, thereby producing information on the dynamics of the food chain. The community approach in the study of the feeding habits of fishes is relatively rare. Prai+ (1946) studied the feeding relationships of six specias of freshwater fish in Lake Vindermere.

## 2.

Hartley $(1940,1948)$ similarly adopted a community approach when examining the feeding habits of both estuarine and freshwater fishes. More recently Keast (1965) and Zaret \& Rand (1971) have examined the resource subdivision among cohabiting fish species in freshwater systems. Studies on the feeding habits of marine fish species have been undertaken by Richards (1963), Nagabushanam (1965) and Tyler (1972). The results of all these studies support the view that a comparative study of the feeding habits of all members of a fish community do lead to a better understanding of the feeding ecology of that community.

Sampling carried out prior to the work described in this thesis had shown that a rich community of inshore fish exists in Loch Etive, comprising some 22 species. The aim of the first part of the present study was to obtain a comprehensive account of the food and feeding habits of the species concerned; to examine the seasonal variation in the quality and quantity of their food and to see how, and to what extent, the available food resources were exploited by the various components of the fish community. The second part of the thesis deals with some behevioural aspects of food selection using two species as examples, with a view to determine if possible, to what extent the feeding behaviour of the fish governs its diet. An extract from this vork has already been published (Kislalioglu and Gibson, 1975).

## Section I - FEEDING ECOLOGY

## SAMPLING AREAS

Loch Etive is a sea-loch situsted on the fjordic coastline of west Scotland. It is a double basin system, linked to the outside sea area by a shallow sill. An account of the hydrography and benthic communities of the loch has been given by Gage (1972). Three areas in this loch each with differont bottom substrates and salinity were chosen for sampling. The sampling areas are shown in Fig. 1. Dunstaffnage Bay has both sandy and rocky bottom substrates; Airds Bay and Dail have shingle ani--ruky bottom types respectively. A decreasing salinity gradient exists from Dunstaffnage Bay to Dail. It was assumed that the sampling of these three stations would ensure a fair representation of all inshore fish species found in the loch.

A. Dungtaffnage Bay, H. Airds Bay, K. Dail. (Prom Gage 1972).

## METHODS

1) Fishing Methods

A 45 m sand eel beach seine and a 1.7 m push net were used for collecting samples. All the fishes raught between 0 to 8 m depth were included in the foc\% analyses. Samples were taken at low water and during the day only, to minimise any possible effects of tidal and diurnal variation in feeding. Shore collections were made at low tide whenever monthly sample sizes were small.

Samples were collected at fortnightly intervals over the 13 month period from October 1971 to October 1972. A total of 3638 fish stomach contents from 21 species were examined.
2) Methods of Pood Analysis

Hynes (1950) reviews the methods available for studying the food of fishes. Briefly sumarised they are: a) The occurrence method:

The number of fish in which each food item occurs is expressed as a percentage of the total number of fish examined. Often the number of occurrences of all items are summed and
scaled down to a percentage casis.
b) The number method:

The total number of individual food items in each food category is listed, often as percentages of the total numbers of animals found in all the fish examined.
c) The dominance method:

The number of fish in which each/food item is the dominant food is expressed as the percentage of the total number of fish examined.
d) The volume and weight method:

The total volume or weight of each food item or of the total food of each fish is calculated, usually as a percentage of the total weight of the fish.
e) The fullness method:

Arbitrary estimations of the degree of fullness of the stomachs examined one used to express seasonsl variations in food intake.

1) The points method:

The food items in each stomach are listed as common, frequent etc, on the basis of rough counts and visual estimation, making allowance for the differences in aize of organisms as
well as their abundance. This means a large animal would count as much as many smallef ones. Each category (comon, frequent etc.) is allotea a number of points and all the points gained by each food item summed and expressed on a percentage scale to give the percentage composition of the diet of the fish examined. Consideration of the fullness of the stomach and the size of the fish affects the number of points allotted; a total number of points is allotted to a stomach on the basis of the size of the fish and the fullness of the stomach and this total is then divided proportionately among the food items present. This is essentially an approximate volumetric method.

Hynes (1950) shows thet all the methods considered give substantially similar results, at least for the major components of the diet.

As the aim of the present study was to investigate and compare the food composition of a large number of species it was necessary to select a method that could be applied to all of them. It was also necessary to choose a method that was relatively rapid and easy so that as many fishes as possible could be examined.

> A preliminary examination of the stomach contents of
selected species showed that the fishes differed widely in the amount and state of food found in their stomachs. Theoretically, the most accurate method would be the weight and volume method; but this method would be practical only when large volumes of food were present and number of items to be segregated was small. This method could be applied with reasonable accuracy to crab-eating cottids for example. In most species, however, because of their small size, the total weight of food was very low and as well as being very laborious, the errors involved in weighing (or in estimating the volume of) very small amounts of food items would be quite large and would lead to a high degree of inaccuracy. This method was therefore considered to be unsuitable for the present investigation.

Examples of the dry weights of the total amount of food found in seven species are given belov to demonstrate this point.

Table 1. Dry weights of the stomach contents of seven species
in November 1971.

## 9.

The numbers method was also found to be unsuitable because the food items in the stomachs of several species were not intact and often only parts were found instead of whole animals. In such instances the numbers could not be estimated accurately. It was also obvious that consideration of the number of various food items found could not give a realistic picture of importance of different foods because of the large differences in the size of individual food items.

It was possible to apply the occurrence and points methods to all species considered. The occurrence method is not affected by the state of the animals found as long as they vere identifiable. It also demonstrates effectively which organisms are being eaten but gives no information on quantities or numbers. The points method does, however, determine the relative amounts of the food items in the diet. It is a rapid and easy method, is not influenced by the frequent occurrence of a small organism in large numbers, nor of heavy bodies and does not involve counting large numbers of small and broken organisms. The subjective allotment of points made by the investigator is the only obvious limitation. Hynes (1950) ergues that although the method is subjective, such subjectivity also applies

The nurbers method was also found to be unsuitable because the food items in the stomachs of several species were not intact and often only parts were found instead of whole animals. In such instances the numbers could not be estimated accurately. It was also obvious that consideration of the number of various food items found could not give a realistic picture of importance of different foods because of the large differences in the size of individual food items.

It was possible to apply the occurrence and points methods to all species considered. The occurrence method is not affected by the state of the animals found as long as they were identifiable. It also demonstrates effectively which organisms are being eaten but gives no information on quantities or numbers. The points method does, however, determine the relative amounts of the food items in the diet. It is a rapid and easy method, is not influenced by the frequent occurrence of a small organism in large numbers, nor of heavy bodies and does not involve counting large numbers of amall and broken organisms. The subjective allotment of points made by the investigator is the only obvious limitation. Hyses (1950) argues that although the method is subjective, such subjectivity also applies
to all other methods. In identifying the broken and often partly digested remains of organisms, ordinary taxonomic characters are usually obscured and the identifications are equally liable to errors and estimating the numbers of broken organisms is also open to inaccuracy.

The method finally chosen was a combination of the occurrence and points methods. It involved estimating the degree of fullness of each stomach. Each stomach was treated as a unit and only the contents of stomachs were included in the analyses as the food in the intestines were often much digested. The fishes were placed in $70 \%$ alcohol immediately after they were caught to prevent further digestion.

The total length, standard length and the mouth gape of each fish was measured, after which the stomachs were removed. It was fairly easy to delimit the stomach from the rest of the gut in most fishes and even in those Iishes where the gut was tubular and no noticeable size differences existed between stomach and rest of the gut, it was atill possible to distinguish the stomach by its relatively thicker walls. The pylorus was taken as the distal limit of the stomach. In some species a large food item vas occasionally found lying in the oesophagus.
to all other methods. In identifying the broken and often partly digested remains of organisms, ordinary taxonomic characters are usually obscured and the identifications are equally liable to errors and estimating the numbers of broken organisms is also open to inaccuracy.

The method finally chosen was a combination of the occurrence and points methods. It involved estimating the degree of fullness of each stomach. Each stomach was treated as a unit and only the contents of stomachs were included in the analyses as the food in the intestines were often much digested. The fishes were placed in $70 \%$ alcohol immediately after they were caught to prevent Purther digestion.

The total length, standard length and the mouth gape of each fish was measured, after which the stomachs were removed. It was fairly easy to delimit the stomach from the rest of the gut in most fishes and even in those fishes where the gut was tubular and no noticeable size differences existed between stomach and rest of the gut, it was still possible to distinguish the stomach by its relatively thicker walls. The pylorus was taken as the distal limit of the stomach. In some species a large food item was occasionally found lying in the oesophagus.

In such cases the food was included in the stomach contents. The most difficult part of the method and which was most subject to a high degree of error was to estimate the degree of fullness of a stomach. 0 to 20 points were used for different fullness categories except where the stomachs were distended which then received up to 30 points. A cut was made along the length of the stomach under a binocular microscope and all the food from the stomach was removed by carefully washing the inside of stomach.

Completely full stomachs offered no difficulty in estimation as the food filled the stomach completely; the wall was stretched thin and encased food closely. Such stomachs received 20 points or if particulerly distended $>20$ points, with a maximum of 30. In completely empty stomachs the walls were thick. Between empty and full stomachs intermediate categories were recognised and a number of points were allotted to the total contents of stomachs accordingly.

As it was obvious that the degree of accuracy depended on experience, a large number of fullness estimation was carried out on most spacies to gain experience. The results are not included in the following food analyses.

After the number of points had been allotted to the total stomach contents according to fullness; the contents vere then sorted into broad food groups such as amphipods, isopods etc. The total number of points was then divided proportionately among these groups making use of a scaled graph paper attached to the table of the microscope when appropriate. If any species or families could be identified asong the food groups, the points received by the group were further subdivided to estimate the relative proportion of different species. The total length of any intact individuals was also measured and the numiers recorded whenever possible.

A set of comparisons was carried out between the percentage composition estimated by points as described above and by measuring the vet weights for 51 juvenile cod to obtain a measure of the eccuracy of the points method. The proportion of different food groups in each stomach was first estimated by the points method then each group was weighed on a microbalance. The weight was expressed as the percentage of the total weight of food. The differences between the two percentages gave an indication of the errors inherent in the points method and also showed whether the points method tended to over-or under-estimate the
amounts of various food groups.
Table 2 gives the proportion of different food groups in each fish in terms of percentage weight and percentage points.

The results showed that proportions of the five food categories in the fish stomachs as estimated by the points method did not differ very widely from those found by the weight method. The signs of the differences showed that in all food groups the points method tended to overestimate the amount of food in each category except in the largest food item, shrimps. The mean differences in the percentages were largest ( $8 \%$ ) in the smallest food item (copepods) but in all others they were between 0.4-5.5\%.

The results suggested that the pcizits method could be satisfactorily used in the estimation of percentage food composition.

For each month the application of the above methods gave the following datas

1) The percentage composition of diet by points. The points received by each food category was expressed as a percentage of the total number of points gained by all stomachs for all food categories.
Table 2. Comparison of the points and weights method of food analysis for 51 juvenile cod

| Food Category | No stomachs containing food category | No of times <br> points estimate <br> $>$ weight <br> estimate <br> (-vedifference) | No of times weight estimate >points estimate (-ve difference) | Maximum <br> -ve difference | Maximum positive difference | Algebraic mean of difference |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Amphipods | 33 | 23 | 10 | -19.03 | +31.56 | +3.94 |
| Shrimps | 26 | 14 | 12 | -26.19 | +14.34 | $\pm 0.88$ |
| Copepods | 7 | 6 | 1 | -10.23 | +24.77 | +8.12 |
| Cumaceans | 11 | 11 | 0 | - | +9.51 | +5.50 |
| Isopods | 8 | 7 | 1 | -21.72 | $+7.44$ | +0.47 |

2) The percentage composition of diet by occurrence. The number of stomachs in which each food category occurred was expressed as a percentage of the total number of occurrences of all food categories in all stomachs.
3) The percentage number of stomachs that were full, $\frac{1}{4}$ full, $\frac{1}{2}$ full, $\frac{1}{4}$ full, trace full and empty and the mean points/stomach/month giving a monthly fullness index.

## RESULTS

The number of fishes caught at the three sampling stations and the number of hauls throughout the sampling period are given in Table 3. It can be seen that the catches from Dunstaffnage Bay, dirds Bay and Dail differed slightly in species composition. More P. microps and G. aculeatus and Anguilla anguilla vere caught at Dail compared to Dunstaffnage Bay and Airds Bay which may be attributable to the low salinity preferences of these species.

The number of hauls shows that Dunstaffnage Bay has been most extensively sampled and Dail least. When the stations were compared haul by haul slightly larger number of fishes with a greater diversity were found at lunstaffnage Bay.
2) The percentage composition of diet by occurrence. The number of stomachs in which each food category occurred was expressed as a percentage of the total number of occurrences of all food categories in all stomachs.
3) The percentage number of stomachs that were full, $\frac{3}{4}$ full, $\frac{1}{2}$ full, $\frac{1}{4}$ full, trace full and empty and the mean points/stomach/month giving a monthly fullness index.

## RESULTS

The number of fishes caught at the three sampling stations and the number of hauls throughout the sampling period are given in Table 3. It can be sean that the catches from Dunstaffage Bay, Airds Bay and Dail differed slightly in species composition. More P. microps and G. aculeatus and Anguilla anguilla were caught at Dail compared to Dunstaffnage Bay and Airds Bay which may be attributable to the low salinity preferences of these species.

The number of hauls shows that Dunstaffnage Bay has been most extensively sampled and Dail least. When the stations were compared haul by haul slightly larger number of fishes with a greater diversity were found at lunstaffnage Bay.

## DIETART COMPOSITION OF INDIVIDUAL SPECIES

## 1. Spinachia spinachia

There is very little known about the food or the feeding habits of S. spinachia. Wheeler (1968) states that the food of this fish is small crustaceans but no detailed information is available concerning the composition or the seasonal variation in diet. Judging from the occurrences in the catches, this fish forms a substantial part of the inshore fish populations in Loch Etive and therefore probably plays an important role in the community structure.

A total of 608 fish stomachs were examined from three different localities during the sampling period. As mentioned, earlier most of the sampling was carried out at low tide and substantial amounts of food were often present in fish stomachs. The state of the food varied; sometimes it was highly digested but it was generally possible to differentiate between the major food groups. The specific identification of food items was more difficult as the parts of the body with taxonomic characteristics were frequently missing. The food items were identified down to species whenever possible.

The list of food organisms encountered during the whole sampling period is given below. The relative importance of each food group in the diet is demonstrated by percentage occurrence (PO) and percentage points (PP). PO values show the proportional occurrence of each group as a percentage of total number of occurrences found in all months. PP values correspond to the percentage points received by each group out of total number of points given to all food groups estimating the proportional amounts of each category. The relative importance of different species of amphipods are shown by calculating PO, PP values for each species separately.

## Local variation in the composition of the diet.

The main food types remained, on the whole, unchanged in the three localities, although Dunstaffnage Bay, Airds Bay and Dail Bay had very different bottom substrata. There vere, however, differences in the relative importance of food groups between the three stations. Amphipods were the most important food group in the samples from Dunstaffnage Bay in all months.

The values of percentage occurrence ( PO ) and percentage

points (PP) were consistently higher for this group than all the remaining groups. In stomachs of fish çaught in Airds Bay, although amphipods were present throughout the year in substantial amounts and were the most important food group in most months, their dominance over all other types of food was not as consistent as in the diets of fishes caught in Dunstaffnage Bay. Isopods occasionally attained primary importance. The same was true for the Dail samples, where amphipods were often the most important group but in some months isopods occurred more frequently and in higher quantities. PO, PP values for isopods were generally higher in fishes caught in Airds Bay and Dail than those caught in Dunstaffnage Bay. In order to test whether samples from the three localities differed significantly with respect to isopods and amphipods, the total number of times each food type vas present and absent in the samples from three stations were compared with a $\boldsymbol{x}^{\mathbf{2}}$ test. The $X^{\mathbf{2}}$ values for these comparisons are given below.

Table 5 shows that the number of occurrences of amphipods in the diet of fishes caught at Dunstaffnage Bay were significantly different from those caught in Airds Bay. No difference was found in the occurrences of amphipods between

Table 5. $x^{2}$ values for the comparis on of occurrence of amphipods in fish stomachs between the three stations.

| Station | Dunstaffnage <br> Bay | Airds <br> Bay | Dail |
| :--- | :--- | :--- | :--- |
| Dunstaffnage Bay |  | $6.81 *$ | 0.87 |
| Airds Bay |  |  |  |
| Dail |  |  |  |

Table 6. $x^{2}$ values for the comparison of occurrence of isodods in fish stomachs between the three stations.

Dunstaffnage Bay and Dail and the difference between Dail and Airds Bay was also not significant. The comparisons support the indication given by PO and PP values that the fishes caught in Dunstaffnage Bay had the greatest frequency of occurrence of amphipods, those from Airds Bay lowest, and the Dail samples have intermediate values.

The differences in the occurrences of isopods in samples from the three localities were much more pronounced (Table 6). The number of times isopods were found in the stomachs of fish caught in Airds Bay and Dail was very significantly higher than in those caught in Dunstaffnage Bay. The differences between the samples from Airds Bay and Dail were negligible.

The examination of PO and PP values from three localities also suggested that although their occurrences in the samples were not continous, mysids might be a more important food group in the diets of fishes caught in Dunstaffnage Bay than in those caught in the other two localities. $\chi^{2}$ values for the comparison of occurrences for the whole sampling period between localities are given below.

Table 7. $X^{2}$ values for the comparison of occurrence of mysids in fish stomachs between three localities.

The number of occurrences of mysids in fish stomachs caught in Dunstaffnage Bay were significantly higher from those caught in Airds Bay and Dail. Once again no differences were found between the samples from Airds Bay and Dail.

The differences between the stations with regards to mysids are likely to be the result of distribution patterns of mysids in the loch. Mysid populations are well established in Dunstaffnage Bay and Dail; Airds Bay may be poorer in this respect, but the distribution of mysids is extremely patchy and. the presence of mysids in the diet of a fish in a particular month probably depends on whether fishes are feeding in the areas where mysids are numerous.

Insect larvae and molluscs also seemed to exhibit a certain degree of local variation. The occurrences of insect larvae in the Airds Bay and Dail samples were significantly higher than in the Dunstaffnage Bay samples. Rivers flow into both Airds Bay and Dail (Fig. 1) and it is likely that they carry to these localities a considerable amount of insect larvae in summer months when their numbers are high.

Table 8. $X^{2}$ values for the comparison of occurrence of insect
larvae in fish stomachs between three localities.

| Station | Dunstaffnage <br> Bay | Airds <br> Bay | Dail |  |
| :--- | :--- | :--- | :--- | :--- |

| Airds Bay <br> Dail |  |  | 0.78 | $* \mathrm{p}<0.005$ |

The number of occurrences of molluscs vere higher in Airds Bay than Dail and Dunstaffnage Bay but the differences were not as pronounced as insect larvae occurrences.

Table 9. $\chi^{2}$ values for the comparison of occurrence of
molluscs in fish stomachs between three localities.

It is well known that in brackish water or in areas with fluctuating salinity the specific diversity of the benthos is much more restricted than in fully saline waters. Gage (1972) has shown that in Loch Etive the number of benthic species is far greater in Dunstaffnage Bay, whose salinity is close to that of the open sea, than in the remaining part of Loch Etive where salinity decreases consistently towards the head of the loch.

Among all the amphipods identified in fish stomachs, 12 species were found in Dunstaffage samples, 9 species in Airds Bay and 7 species in Dail. The percentage of unidentified amphipods in Dunstaffnage Bay was also greater than the other
two localities. This may be a reflection of the differences in specific diversity of the three localities imposed by the salinity gradient that exists between Dunstaffnage Bay and Dail.

Table 9 gives the relative importance of different species in three stations.

The greatest percentage of amphipods both in occurrence (PO) and bulk (PP) were Gammarids in all three localities. The only amphipods which showed a clear local variation were the family Corophidae. These amphipods were the second most important amphipods at Dail both in terms of their percentage of occurrence and volume. The differences between Dail and both Dunstaffnage and Airds Bay samples vere significant at $p<0.01$.

Hyale sp. were found to occur more frequently in the Dunstaffnage Bay and Airds Bay samples, where they were the second most important types of amphipods, than at Dail.

diet in each month throughout the sampling period.
The number of main food groups in the diet of S. spinachia were found to be relatively $f e w$, and they showed very little variation throughout the year. Amphipods on the whole were the most important food item. They had the highest PO and PP values among all food groups in most months except in November and December when isopods became the primary food group, and in July when harpacticoid copepods became most important. In some months amphipods formed up to 75\% of the total amount of food. The greatest portion of amphipods consisted of gammarids throughout the year, with the exception of July when they were absent. In this month Amphithee and Hyale spp kecame important. The lack of gammarids in the July sample is thought to be a result of size-related food selection. The total length of the fishes caught in July varied between 35 and $57 \mathrm{mm}$. . On the whole, as fish size increased the proportion of gammarids in fish diets also increased:

No other amphipod group has the same importance in the fishes diet as gammarids, although the amount of Hyale sp. reached high levels in January, June, July and August. The importance of Corophium sp. in the diet increased in the spring months, March,

April and May. Whether the increase was a reflection of a change in the abundance of this species is not known.

Isopods formed the second most important food group all the year round (Fig 2). The greatest proportion of isopods consisted of Jaera sp. Mysids on the whole were third in importance in the diets of $S$. spinachia; their occurrence seemed to exhibit some seasonal variation. The sampling period could roughly be divided into two parts with respect to the importance of mysids. They were the third important food category from October to December; their significance decreased during the late winter and early spring and increased again in May, June, September and October. This agrees well with the seasonal abundance of mysid populations in the loch. The biology of Praunus flexuosus and the brackish water species Neomysis integer have been well studied in Loch Etive (Mauchline 1971). In December the large population of Praunus flexuosus in Dunstaffnage Bay consists predominantly of juveniles and immature males and females; breeding çontinues throughout the winter but at a greatly reduced intensity. The proportion of juveniles in the population decreases in January and Pebruary. In March and April juveniles mature sexually reaching larger
sizes. From June to October the number of very young juveniles increases again. During these months, except July, mysids also become an important component of the fishes diet.

In July 1972, mysids were not found in fish stomachs. This could be explained by the fact that all fishes caught were juveniles with a mean total length of 42 mm . When the occurrence and the quantity of mysids in different fish size groups were examined, it was found that mysid feeding begins to be important in fish above 70 mm total length. In July, the lack of mysids in the fishes diet is though to be related to the fish sizes being smaller than the size at which mysid feeding begins.

The monthly composition of the population of Neomysis integer found at the head of Loch Etive and at Dail gives essentially the same picture as Praunus flexuosus. As in Praunus the number of small sized very young juveniles is high in December, decreases in January and they are rare until late May, becoming abundant again from July onwards. Hence the summer and autumn generations contain many small sized juveniles with total size range between 4-14 man, a size suitable for predation by the fish. The $90-100 \mathrm{~mm}$ size group of Spinachia
which was the commonest size group in the catches feeds mostly on mysids of the size range $5 \mathbf{- 1 5} \mathrm{~mm}$.

The variations in the seasonal importance of mysids in the fishes diet seem to be affected therefore by three factors. First, iy the seasonal abundance of mysid populations, secondly, seasonal differences in the total length of the fisis in the samples and thirdly by local variations between samples due to the patchy distribution of mysids. This may serve as an example of a case where misleading conclusions may be drawn if all possible factors causing dietary variation are not taken into account.

Another example of the food group whose occurrence in the fish diets is a combined result of the factors mentioned above are insect larvae. Table 11 and Fig 2 show that this group has a clear seasonal variation. Insect larvae were important in fish diets from early summer to autumn. Percentage occurrence and percentage points were very low in the winter months. Insect larvae gained importance once again in the spring and retained this position until October. Their increasing abundance as well as small size rendered them a suitable food item for the juveniles which were mostly present in the sumer months. As mentioned earlier, this food group also showed considerable
local variation.
Molluscs, especially gastropods occurred frequently in fish stomachs in most months, but they never became an important part of the diet. Their occurrence increased slightly in winter months when the overall feeding intensity was low and their importance in the diets is likely to be accentuated in the winter due to the low levels of food found in the stomachs.

Harpacticoid copepods occurred fairly regularly in all months although their PO and PP values were very small. Their importance in the diet of Spinachia increased considerably in the summer months, especially in July, where they formed the greatest portion of the jurenile fishes diet. The mean total length of fishes in the July sample was the lowest among the summer months. The variation in the amounts of harpacticoids thus seems to depend primarily on fish size and not season or locality.

The frequency of occurrence and the volume of calanoid and ostracods in the diet of Spinachia throughout the year is similar to that of harpacticoids. Although these groups never became an important part of the diet, their numbers increased from May onwards: September values for the planktonic copepods were the highest and this month was unusual in the sense that
some adult fishes turned to planktonic feeding habits and had taken large quantities of planktonic copepods. In this case their consumption was not clearly related to fish size. No explanation is available for such a change except that they may have come across a shallow water plankton patch. It demonstrates that although the fishes are primarily benthic feeders, under certain circumstances they can feed on zooplankton. They thus show a certain degree of plexibility in their feeding habits and are not compulsory benthic feeders.

Polychaetes were not an important group in Spinachia's diet; they occurred irregularly in some months but never in large quantities. Oligochaetes were recorded only once.

## 2. Gasterosteus aculeatus

G. aculeatus is essentially a freshwater species although its distribution extends to estuaries and sometimes well into the sea. In Lọch Etive, out of 360 fishes examined throughout the sampling period, 108 were caught in Dunstaffnage Bay where marine conditions were prevailing, only 8 were caught in Airds Bay and 244 were caught in Dail which had the lowest salinity. Several early authors give lists of food of the three-
spined stickleback, Day (1880-4), Smith (1892) Tate Regan (1911) also Bertin (1925), Leiner (1930) Heilborn (1931) and Fisher (1948). Their results agree that the diet of G. aculeatus consists of worms of various kinds, small crustacea, aquatic insects, larvae, occasional aerial insects and fish eggs.

Saunders (1914), Blegvad (1917), Hartley (1940) and Hynes (1950) have made more detailed studies of the food of this species. Saunders examined a large number of sticklebacks from a pond near Cambridge and found at all times of the year larger fish consumed large quantities of diatoms, whereas smaller fish were carnivorous, feeding on insect larvae and crustacea; in nearby ponds all fish were carnivorous.

Blegrad (1917) investigated the stomach contents of 736 fishes from the brackish waters of the Zostera region of various Danish weters. He states that young fish feed on copepods, cladocerans, mollusc larvae and ostracods and as they grow they begin to eat young gammarid amphipods, isopods and mysids, also the eggs of fish.

Hartley (1940) examined the stomach of 129 fishes from two Cambridge rivers. His results, assessed by the occurrence method,
show that insects formed $60 \%$ of the food and crustacea $29 \%$, small molluscs and some plant material were also present. Crustacea vere the most important food in the winter; in the other nine months of the year insects predominated.

Hynes (1950) analysed the food of fishes from a small stream in Westmorland and from Easdale Quarry in Argyllshire. He found that the main food groups were Cladocera, Copepoda, Ostracoda, insect larvae, Annelida and Mollusca.

The list of the food items found in the stomachs of G. aculeatus and relative importance of food groups shown by percentage occurrence, percentage point values are given below (Table 12).

Table $13^{*}$ gives the PO, PP values for different food groups throughout the year for the combined localities.

Amphipods occurred consistently in fish stomachs in considerable amounts. The percentage occurrence values for this group varied between 1-32 and percentage point values 1-52 (Fig 3). The lowest PO and PP values for amphipods were found in August and September. Percentage point values, which are the estimates of the amount of food in Pish stomachs, were often higher than the percentage occurrence values in terms of the

volume of the dret, amphipods were the most important food item during the months November, January, January, March, May and July. The relatively low occurrence and amounts of amphipods in fish stomachs in August and September is most likely due to the extremely small size of fishes in these months samples. More than $85 \%$ of the fishes caught in July and August were below 30 mm . Amphipods were, on the whole, more frequent in fishes above 40 mm total length. Hynes (1951) likewise comments on the tendency of larger
fishes to feed on larger crustacea.

Among amphipods Corophium sp was the most frequently occurring amphipod, followed by gammarids. Other amphipod types were much less common.

The occurrence of zooplankton (calanoid copepods, cladocerans, cirripede nauplii, planktonic prosobranchs, etc) was not continuous in all months but whenever found they were taken in large quantities. In terms of PO and PP values they were highly significant in October, November, February, August and September. In general, copepods produce a succession of broods throughout the summer Marshall (1949). It is, on the vhole, true that small copepods such as Temora sp, ${ }^{\text {and }}$ Pseudocalanus sp. are more numerous in spring and summer than in winter but it was not possible to follow this trend from the PO, PP values for calanoid copepods; for example they are poorly represented in the April, June, a.July samples. The occurrence of zooplankton in fish stomachs seem to depend on fish size as well as the seasonal abundance of plankton. Generally, the amount of zooplanhton was found to be greater in smaller fishes. The largest proportion of plankton consisted of calanoid copepods, but the amount of cladocerans were exceptionally high in August and September.

Among amphipods Corophium sp was the most frequently occurring amphipod, followed by gammarids. Other amphipod types were mich less common.

The occurrence of zooplankton (celanoid copepods, cladocerans, cirripede nauplii, planktonic prosobranchs, etc) was not continuous in all months but whenever found they were taken in large quantities. In terms of PO and PP values they were highly significant in October, November, February, August and September. In general, copepods produce a succession of broods throughout the summer Marshall (1949). It is, on the whole, true that small copepods such as Temora sp, / Pseudocalanus sp. are more numerous in spring and summer than in winter but it was not possible to follow this trend from the PO, PP values for calanoid copepods; for example they are poorly represented in the April, June, dJuly samples. The occurrence of zooplankton in fish stomachs seem to depend on fish size as well as the seasonal abundance of plankton. Generally, the amount of zooplankton was found to be greater in smaller fishes. The largest proportion of plankton consisted of calanoid copepods, but the amount of cladocerans $w$ exceptionally high in August and September.

Insects were well represented in/fishes diet, often occurring in large quantities in most months (Fig 3). In S. spinachia it was shown that the occurrence of insect larvae was significantly higher at Dail than in Dunstaffnage Bay. Local differences in the abundance of this group may be the reason for the ir abundance in G. aculeatus as most of the fishes were caught at Dail. In October 1971, for example, insect larvae were present in very large quantities in the Dail sample, but they were almost absent in Dunstaffnage sample. Terrestrial and aerial insects also frequently occurred in most months, but on the whole they were not as important as insect larvae, except in July and November.

Harpacticoids were an important food group, present in all months except July (Fig 3). Their significance in fish stomachs, like that of planktonic copepods, seemed to depend primarily on fish size. They were better represented in the months where the proportion of smaller fishes in the sample was large.

Isopods and polychaetes occurred in most months samples in varying quantities; neither of them showed a seasonal pattern. The mosi common isopod was Taera sp. Oligochaetes
were found in Pish stomachs in May, June and July with relatively high $P 0$ and $P P$ values.

The other food groups such as rysids, Decapoda, Nemertini and molluscs were very poorly represented in fish stomachs. They occurred very occasionally and in small quantities.

Plant matter formed a small proportion of the food and appeared to be taken accidentally in most seasons. No individual stomachs contained a large amount of plant matter, unlike Saunders (1914) and Blegvad's (1917) results.

One juvenile flatfish of 11 mas was found in May in the stomach of a 56 mm specimen:
3. Myoxocephalus scorpius

This fish is not restricted in its habitat and can be found equally on sandy, muddy and rocky bottom substrate. The largest numbers in the present investigation were caught in Dunstaffnage Bay, probably as a result of more intensive sampling carried out at this location.

The food and feoding habits of $M_{\text {, scorpius }}$ hive not been thoroughly investigated and the only references to its food are found among the early literature. More recent work covers the
age, growth and bionomics of this fish (Ennis 1963, Lamp 1966). Wheeler (1968) mentions that M. scorpius feeds on a wide range of food items, intertidal specimens mostly eating amphipods, especially gammarids, decapods (shore crabs), polychaete worms and fishes. Sublittoral populations feed on the same types plus mysids and shrimps.

Blegrad (1917) determined the food composition of 233 Danish M. scorpius varying in length from $80-270 \mathrm{~mm}$, and expressed the importance of the various food types by the weights method. He found that more than half of the weight of total food contents consisted of various small fish such as sticklebacks, gobies, pipe fish, sand eels, herring, small cod, eel, Zoarces and whiting. The second most important group by weight was crustacea. In the Zostera region the main crustaceans were Idotea Gammaridse, prawns and crabs. Outside the Zostera belt the food consisted mostly of shrimps. Polychaete worms formed a small proportion of the diet and molluscs vere negligible. Larsen (1935) also gives a short description of the food of M. acornius from Danish waters. He lists the numbers of occurrence of various food items found in stomachs of 33 specimens, varying in size netween $120-260 \mathrm{~mm}$. The percentage occurrences of
the different food types were calculated from his figures in order to compare the food composition with the results of present investigation. Larsen found that shrimps had the highest frequency in fish stomachs, Leander sp being found to occur more frequently than Crangon vulgaris. Juvenile Pish was the second most important food group in terms of occurrence, followed by amphipods and isopods. The frequency of occurrence of insect larvee, molluscs and mysids was very small.

In the present investigation a total of 232 fish stomechs were examined, most of them caught in Dunstaffnage Bay.

The list of food items found in the diet of M. scorpius and relative importance of food groups in the pooled samples are given below (Table 14).

The PO and PP values for the different types of food found in fish stomachs throughout the year are given in Table 15*. Pebbles occurred in most fish stomachs in all the months, especially in large specimens, reflecting the fishes habits of living and feeding among rocky substrata. The occurrence of sand and stones was noted but they were not expressed in terms of percentage occurrence and percentage points as they cannot be considered as food items.

DIGESTED MATTER
```

The main food items of M. scorpius are relatively few, namely crabs, shrimps, amphipodes, fish and mysids. The types of food remained relatively constant throughout the year. The proportions of different food items varied, chiefly with the size of fish present in the samples.

Decapods, namely crabs and shrimps,were present in very large quantities in all months, making up about half or more of total amount of food except in June and July (Fig 4). Shore crabs were a very important constituent of the diet, occurring in all months except July, often making up one third of the total food. When large fishes were present in the samples the PO and PP values for this group were very high. Among the crabs identified, Carcinus maenas occurred most frequently, followed by other species. Hermit crabs vere least frequent.

Shrimps, too, were very common in the stomach contents throughout the year, the mean PO and PP values for the whole sampling period were lower than crabs; Crangon sp was the most commonly occurring shrimp.

Amphipods were found in fish stomachs in every month; their percentage occurrence values were generally high though not as high as those for crabs, except in June and July. The overall

Fig. 4. The seasonal variation in the percentage occurrence and quantity of various food groups in the diet of Myoxocephalus scorpius. Symbols as Fig 3.
a) Amphipods
b) Decapods
c) Fish

P0 and PP values for this group are higher than Decapods due to the exceptionally large quantities found in June and, especially, July samples. Table 15 shows that in all other months amphipods had much lower PO and PP vaiues than Decapods. Their importance in the diet varied directly with the fish size throughout the year, otherwise they did not show a seasonal trend. For example, their importance increased three and four fold in June and July where the fish in the samples were small. $67 \%$ of the June samples consisted of juvenile M. scorpius under 50 mm ; in July $87 \%$ of the fishes were between 21 and $52 \mathrm{~mm} ; 46 \%$ of total sample alone were in 30 mm size group. In 30 mm to 50 mm size group pratically all the food consisted of amphipods. The proportion of different types of amphipods varied in different size groups. Among all the amphipods identified gamarids were of primary importance, followed by Ampelisca sp and Corophium sp.

Ostracods and harpacticoid copepods only occurred in the June and July samples. Their overall importance in the diet was negligible.

Fish commonly occurred in the stomachs of larger specimens and their frequency of occurrence depended on the numbers of large
fish in the samples. $P O$ and $P P$ values for this group, on the whole, were not as high as those for crabs. No seasonal trend was apparent as the samples in most months showed a large size variation. The $P 0$ and PP values indicate that if the Pish was large enough it preyed upon other fish regardless of the time of the year and fish species; juvenile members of the same species were also taken. In October 1971 a 20 mm P. minutus was found in the stomach of a 57 mm fish and in July, a cottid of 11 mm was found to have been taken by a fish of 45 mm . Apart from these two occurrences, specimens with fishes in their stomachs were found to be greater than 120 mm in total length.

The occurrence and the amount of mysids in $M$. scorpius diets did not show any regular seasonal pattern. Percentage occurrence values for mysids were often higher than PP values, sometimes as high as those for shrimps.Mysica were relatively common between October and March.

Polychaetes became a relatively important food group only in Pebruary and March. They also occurred in November, April, May and October 1972 samples in small quantities. Members of the families Nereidae and Arenicolaidae were mostly taken.

Molluscs occurred infrequently in fish stomachs in small quantities between October and February and also in May and July. PO values for this group were always higher than PP values. Isopods, insect larvae and fish eggs were similarly found in a fev fish stomachs throughout the year and never became a substantial part of this fishes diet. Insect larvae occurred only in the spring and sumer months. Larsen's (1935) and Blegrad's(1917) results vere converted to percentage occurrence and percentage weight values and compared with the PO and PP values found in the present investigation. Spearman's Mank correlation was used for the comparisons (Fritz 1974 ). A closer correlation was found between Blegrad's percentage weight values and PP values of the diet of fishes of Loch Etive ( $r_{s}=0.72, n=13, p<0.01$ ) than between Larsen's P0 values and those of the present study $\left(r_{s}=0.51, n=12\right.$, p<0.05).

Larsen's (1935) results differed mainly in the absence of crabs, smaller bodied food groups such as harpacticoids, fish eggs and the much higher significance of isopods.

The main differences between Blegrad's (1917) results and the results of present study were the much higher importance of
fishes as a food group in Nyborg Fjord. Isopods were also a more significant group, whereas in the Loch Etive samples amphipods occurred in greater quantities and smaller bodied food groups were also present.
4. Taurulus bubalis

This fish is closely related to M. scorpius. It is confined mainly to rocky bottoms with a reasonable amount of seaweed cover. The food of T. bubalis is relatively well known compared to the other species previously examined. Early workers (Yarnell, 1859; Couch, 1863; Gosse, 1865; Murie, 1903) all mention that $T$. bubalis feeds mainly on small crustacea and fish. Blegrad (1917) and Hartley (1940) gave some details of the diet based on the stomach contents of two and three fish respectively.

Rice (1962) gives the first detailed account of the food of T. bubalis in Manx waters. He examined a large number of specimens collected intertidally and sublittorally. The relative importance of various food items in the diet was assessed by the points method. He found that the main food groups were Decapoda, Amphipoda, Teleostei and Isopoda in that order. He came to the conclusion that decapods, isopods
and tanaids were more important food items in the intertidal than in the sublittoral fish, whereas mysids and teleosts were of greater importance in sublittoral specimens. Also, larger fish fed more on decapods and teleosts and smaller fish took more tanaids, copepods, insect larvae and isopods.

Western (1969) gives a brief account of the diet of T. bubalis and compares it with Cottus gobio, concentrating mainly on the morphology of alimentary canal. He mentions that fish of 4-8 cm in length feed mainly on amphipods and other small crustaceans. Gibson (1972) found that T. bubalis on the Atlantic coast of France fed primarily on amphipods and secondarily on brachyuran decapods. Isopods, copepods, molluscs and polychaete also had relatively high frequency of occurrence values in the diet.

A total of 116 specimens from Loch Etive were examined. The food composition list and the percentage occurrence and percentage point values for the food groups are given below. (Table 16).

It will be seen from the overall $P 0$ and $P P$ values and their monthly variation (Table $17^{*}$ \& Fig 5) that amphipods were the most important food item in the diet of $T$. bubalis in Loch Etive. The presence of amphipods in the fishes diet

INDET. MATERIAL
was consistent through the year and their PO, PP values were above $22 \%$ in all months sampled. Percentage point values, which measured the amount of food in fish stomachs, were often higher than percentage occurrence values. In the summer months, especially, amphipods formed up to $79 \%$ of the diet. The most important amphipods were gammarids, followed by Corophium sp. The other types listed were much less frequent. The greater importance of amphipods in the summer months may be a result of the greator proportion of juveniles in the samples. Rice (1962) states that in the smaller intertidal Manx fish, amphipods become the most important food in April-June. In the period from July to September, unlike Loch Etive Pishes, isopods became the main
constituent of the smaller fishes diet.
Insect larvae were absent in the winter months but appeared sporadically in the stomachs of smaller fish between March-October. They always had higher frequency of occurrence values than percentage point values and were never of great significance in the diet.

Polychaetes were the second most important food group in the diet of T. bubalis in Loch Etive. They were present in all samples. The monthly variations in the PP values show that the volume of polychaetes in the fishes diets was higher in the vinter months than in the summer months, (Pig 5). Their occurrence did not demonstrate a seasonal pattern. Members of the families Phyllodocidae and Nereidae were most common.

The occurrence of isopods was continuous throughout the year except in March and August. Their percentage occurrence values vere sometimes as high as those for polycheetes but because of their relatively small volume they had much lower PP values. The greatest proportion of isopods consisted of Jaera sp, the larger isopods, Idotea sp and Spheeroma sp vere less frequent. Hice (1962) found that isopods vere mainly eaten in the first and third quarters of the year by the larger fish and in
the third quarter by the smaller fish. Fig 5 shors that PP *alues for isopods were highest between May and July and the peak in June may reflect the higher degree of isopod feeding by juvenile fishes in this month.

The main food of $M_{\text {. scorpius, }}$ decapods, were much less well represented in the diet of T. bubalis. Crabs were more important than shrimps (PO, PP values $8 \%, 10 \%$ and $3 \%, 5 \%$ respectively). This difference may indicate that the greatest proportion of the fish caught were intertidal and not sublittoral Wheeler (1968). If this was true, it might also explain the low numbst, of teleosts found in fish stomachs since Rice (1962) demonstrated that teleosts are of greater importance in the diets of sublittoral specimens than of intertidal fish. The overall PO, PP values for teleosts vere under 10\%. They appeared irregularly in the samples between October and April and were absent in the summer. Like crabs and shrimps they were found in the stomachs of larger specimens.

Molluscs were more important in the diets of the fish in the winter than in summer months. In November and February they were the third most important food group in terms of PO, PP values. Their occurrences in fish stomachs were negligible
during the sumier months.
The results of the present study differ from those of Rice (1962) in several respects. In the diet of Manx fishes decapods and amphipods were of primary importance, followed by teleosts and isopods, the percentage point values for polychaetes being much lower. In Loch Etive, amphipods were of much greater significance than all remaining groups, the occurrence and amounts of polychaeta were also much higher, forming the second most importent food group, decapods being third. Isopods and teleosts were more poorly represented in the diet of Loch Etive fish.

On the basis of these results it was concluded that although M. scorpius and T. bubalis have seemingly overlapping diets (see species composition list) they differed considerably in the proportion of their principal food. M. scorpius took more shore crabs and shrimps whereas T. bubalis fed more heavily on amphipods and polychaetes throughout the year.

## 5. Pholis gunnellus

P. gunnellus has a wide geographical distribution, being found on both sides of Atlantic. The first information on the
food of this species in the western Atlantic was given by Stroud (1937). This species diet was later examined by Sawyer (1967). In the eastern Atlantic Qasim (1957) gave the first account of the food of P. gunnellus from North Wales.

Stroud (1939) found that the main food groups in the diet of rock gunnels were Polychaeta, Amphipoda and Isopoda. Qasims (1957) results showed that in addition to these groups, barnacles and decapods were an important part of the diet of this species on the east side of Atlantic. Sawyer (1967) listed the main food groups as Amphipoda, Isopoda, Decapoda, insect larvae and Molluscs. On comparing his results with Stroud's and Qasim's he came to the conclusion that this species apparently feeds on similar organisms on both sides of Atlantic.

281 specimens were examined in Loch Etive. The food composition list and the percentage occurrence and percentage points values for each food group are given below. (Table 18).

It is evident both from Table 19*and Fig 6 that the most important food item in the diet of this species caught in Loch Etive was amphipods. The percentage occurrence and percentage points values for this group were above $20 \%$ in all months.

INDET. MATERLAL
PP values were higher than po values throughout the year. Both indices showed that amphipods were the most frequently occurring animals in fish stomachs as well as constifuting the bulk of the diet. No seasonal variation in their occurrence was found.
Among the amphipods which could be identified, gamarids occurred most frequently and were present in most months samples.
```

Microprotopus sp has also a high frequency of occurrence. Other species found frequently were Amphithoe sp, Corophium sp, Nototropis sp, and members of the family Caprellidae.

Isopods were the second major group. They were present in all months except March which was also the smallest sample, the number of fish stomachs sontaining food being only three. They were not always the second most important group in terms of numbers and amounts. They appeared more important if their frequency of occurrence only was considered, but they usually formed a smaller fraction of the total amount of food in a months sample. This is clearly seen when $P 0$ and $P P$ values are compared. Most of the specimens vere caught in Dunstaffnage Bay, therefore most monthly values demonstrate the dietary composition at this location. It was shown in the food analyses of S. spinachia that there was a clear difference in the occurrence of isopods between Dunstaffnage and Airda Bay and the overall low values for the frequency of occurrence of isopods in $p$ gunnellus may reflect this local variation and may not be a true estimation of the selection shown by the fish. Qasims (1957) values for the occurrence of isopods in fish
stomachs were much higher than those found in the present study.
Polychaeta were present in most months except in March, August and September. In October, November and Pebruary they formed a large portion of the total amount of food found in the stomachs and became the second most important food group. Their actual amount is likely to be greater than those indicated by PP values because polychaete remains were often found in form of bristles and fragments of the body. Fig 6 suggests that they may be more significant in the diet in colder months than in the summer.

The greatest proportion of Copepoda consisted of harpacticoids. Harpacticoids vere found to be an important part of the diet of P. gunnellus in Loch Etive. Their occurrence in fish stomachs showed a clear seasonal pattern. Fig 6 shows that they gained importance as a food group between April and August and were not significant in other months. They were the second most important food group in terms of occurrences and quantities in April and July. Calanoid copepods were poorly represunted. They vere present in most months samples in small numbers but never became an important constituent of the diet.

Ostracods occurred fairly regularly in most months with

P) Polychaetes.

relatively high frequency of occurrence values and sometimes in considerable numbers. The monthly variation in PO and PP values suggest the presence of some seasonal trend. Like harpacticoids, they appear to be more important in spring and summer than at other times. Percentage occurrence values for ostracods, like harpacticoids, were always higher than percentage point values. This difference between PO and PP values demonstrates the overestimation of the importance of a small sized food group by the occurrence method and underestimation by the points method as mentioned earlier. As ostracods regularly occurred in most months and in Pairly high numbers however, their significance in the diet of P. gunnellus is quite clear.

Molluscs, mainly small bivalves, were present in most months samples in small numbers. Their contribution to the total amount of food in each month's samples were small. In the months when they occurred together with ostracods, ostracods. almost always had higher PO, PP values and though both groups appeared in nine out of 12 months examined, ostracods vere clearly the more important constituent of the diet.

The occurrence of insect larvae and insects in fish stomachs
showed the most marked seasonal trend among all the food groups. They were present, but not in significant amounts in October 1971, then diminished throughout the winter, reappearing in May, occurring frequently and in large quantities. They were particularly important in September when the whole sample consisted of fishes caught at Dail and Airds Bay. In S. spinachia it was shown that more insect larvae were present in these two localities than at Dunstaffnage Bay. As in the case of isopods, the importance of insect larvae in the diet of $P$. gunnellus could be underestimated because of the fact that most specimens were caught in Dunstaffnage Bay.

Shrimps and crabs occurred occasionally and in low numbers. Decapoda other than crabs were often present in fish stomachs in the form of portions of the head and eye stalks. As they vere not found as whole animals the estimated PP values are likely to be lower than the actual amounts consumed. But as their occurrence was also low and they did not appear regularly in the samples, it can be concluded that they were not an essential part of the diet.

The occurrence of mysids in the monthly samples was
irregular, they were often broken or in a digested state.
Other food groups which occurred occasionally and in low numbers were barnacles and cumaceans.

When the food composition of P. gunnellus from Loch Etive is compared with that of specimens from North Wales, Qasim (1957), the food categories on the whole are found to be similar in both places; there are however differences in the relative importance of various groups in the diet. Amphipodswere the most important food group for Loch Etive and polychaetes, isopods and decapods were less well represented in the diet when compared to the fish from North Wales. Harpacticoids and outracods were also of higher significance whereas barnacles, which were an important part of the diet of this fish in North Wales, were not significant.
6. Pomatoschistus minutus

This is the common sand goby found on sandy and muddy substrates. Although it is a marine species it also enters estuaries. In Loch Etive, the highest catches were made in Dunstaffnage Bay. The stomach contents of 391 specimens were examined.

The earliest account of the food of P. minutus is given by

Blegvad (1917). He found that in Danish waters the diet of this species consisted of pelagic and benthic copepods, amphipods, mysids, shrimps and molluscs. Miller (1963) also examined the food of P. minutus. He found its diet mainly consisted of Grustacea, Rolychaeta and also Mollusca. Macer (1967) found that P. minutus from the Red Wharf Bay (North Wales) also fed mainly on amphipods and secondarily on polychaetes and copepods. Hesthagen (1971) found that the main food groups in the diet of P. minutus from the Belt sea were Polychaeta, Copepoda, Mysidacea and Amphipoda. Healey (1971) who studied the distribution and abundance of P. minutus $^{\text {in }}$ the Ithan estuary found that amphipods had the highest frequency of occurrence in the diet, followed by mysids, isopods and shrimps. The food composition list and PO, PP values for each food group in specimens from Loch Etive are given below (Table 20). The major constituent of the diet of P. minutus in Loch Etive was amphipods. Fig 7 and Table $21^{*}$ show that they occurred in very high quantities all the year round, sometimes forming $90 \%$ of the diet.

The most commonly occurring amphipods in the diet, according to the order of importance were 1). Ampelisca sp,

| 2) Corophium sp, 3) Microprotopus sp. Other amphipods such |  |  |
| as Ampithoe sp, Gammarids, Hyale sp, Nototropis sp were less |  |  |
| common. Ampelisca sp was always found in high quantities in all |  |  |
| the months, forming the greatest proportion of recognisable |  |  |

amphipods, except in July, August, September when Corophium sp gained primary importance. Microprotopus sp also occurred fairly regularly but in much smaller quantities, becoming especially important only in July. Healey (1971) found that in P. minutus from the Ythen estuary, Corophium sp was by far the most important amphipod all the year round and does not mention Ampelisca sp. Loch Etive fishes appear to differ from those of Ythan estuary in this respect.

Polychaeta were the second important food group in the diet of P. minutus. They were taken frequently, but in relatively small amounts. $P 0$ and $P P$ values exceeding the $10 \%$ level only in October 1971, January, April, September 1972. (Fig. 7). Their monthly occurrences, like those of amphipods did not show a seasonal pattera.

The greatest part of the decapods in $P_{\text {. minutus }}$ stomachs consisted of Natantia; crabs formed a very small fraction of the total food. Common shrimp, (Grangon sp) were the most frequently occurring form. Fig 7 suggests that the importance of decapods in P. minutus vas highest between April and July.

The occurrence of mysids was not consistent throughout the year. (Fig. 7). They were absent in the winter and early spring,
having high percentage frequency and percentage point values between August and September. The occurrence of insect larvae in fish diets followed a similar pattern. They were insignificant during late autumn, winter and early spring, were found in fairly high numbers between July and September and then decreased once again in October.

Other less important food groups which occurred from time to time without any apparent seasonal pattern included isopods, molluscs, ostracods, cumaceans and harpacticoids. Harpacticoids, cumaceans and ostracods occurred very infrequently and in negligible quantities.

Planktonic food, mainly in the form of calanoid copepods were taken in three months, October, December and May. In all these instances only planktonic food was found in some stomachs. Although this plankton feeding did not persist, it was important in demonstrating the versatility of feeding in this species.

## 7. Pomatoschistus microps

P. microps is found in intertidal areas on sandy or muddy shores. It prefers low salinities and is common in estuaries. In Loch Etive most specimens were caught at Dail where the
salinity is lowest of three stations sampled. The stomach contents of 95 specimens vere examined.

The biology of $P$. microps was studied by Miller (1963) and later its diet was examined by Mus (1967). Mus found that young fish fed exclusively on young copepods and other juvenile stages of crustacea in the meiofauna. As the fish became larger, adult harpacticoids and polychaetes increase in importance.

Because the monthly samples for this fish were often small, the results have been pooled and only a brief analysis of seasonal variation attempted.

Amphipods were the primary food group all the year round, Corophium sp being the most commonly occurring species (Table 22). Polychaetes were of secondary importance. Among other food groups harpacticoids occurred quite frequently but other copepods were poorly represented. Table $23^{*}$ shows the relative importance of various food groups in the four quarters of the year.

## 8. Chaparrudo f'lavescens

This goby differs from all the other inshore species in

* See Appendix

Table 22. The food composition and the relative importance of various food items in the diet of P. microps.

being much less dependent on the sea bed. They are found in small shoals near the surface and around seaweeds. The literature on the food of C. flevescens is limited. Wheeler (1968) gives the food of this species as copepods, mysids, gammarids and isopods. Hesthagen (1971) examined the stomach contents of only 3 specimens. He found Copepoda, Amphipoda and bivalves were the predominant food items. In Loch Etive a total of 389 specimens were examined. They were mostly caught in Dunstaffnage Bay and Airds Bay.
C. flavescens from Loch Etive was predominantly a plankton (Table 24 ) feeder. $\mathcal{K}$ With the exceptions of December, Pebruary and July, plankton occurred in most stomachs and provided the bulk of the food in each months sample. The February samples was exceptionally small ( $n=7$ ) and only two stomachs contained food which consisted of mysids. In December and July the fish were found to be feeding solely on benthic food.

The majority of the planktonic food in the fish stomachs consisted of calanoid copepods. Fig 8 shows that their occurrences and amounts were high in all months except the three months mentioned above and April. In April the primary importance of calanoid copepods in fish stomachs was replaced

by cirripede nauplii.
Anong the calanoid copepods eaten, Temora sp, Pseudocalanus sp, Paracalanus sp and Acartia sp had especially high frequency of occurrences, Centropages sp and Calanus sp being less common. Among the cyclopoids Oithona sp was Prequent. Harpacticoid copepods were present in most months in small quantities. The percentage occurrence and percentage points were $4 \%$ and $2 \%$ respectively.

Among the plankton food in C. flavescens diets, cirripede and cladocerans were also common, they occurred in much smaller quantities than calanoid copepods. Their occurrence and abundance in fish stomachs showed a more seasonal pattern than that of calanoid and cyclopoid copepods. Cladocerans were most abundant between June and August. The highest occurrences of cirripede nauplii were recorded in April, May and August. Cirripedes were present in considerable numbers in the October 1972 sample in the form of cyprids.

Polychaete larvae, decapod larvae and ostracods were also found among the zooplankton in the fishes atomachs, but their occurrences and numbers never reached significant levels. Nolluscs were also poorly represented. They mostly consisted of
small planktonic gastropods.
Amphipods were found in fish stomachs in small quantities in most months (Table $25^{\text {t }}$ ) often mixed with zooplankton organisms except in December and July when they became the most important food group. In these two months commoner benthic amphipods such as gammarids, Corophium sp, Nototropis sp were found in relatively high quantities. The amphipods found together with the zooplankton in fish stomachs could not be identified. They did not however belong to the fully planktonic family Hyperiidae which were easily recognised by their head being distinctly marked off from the mesosome and by their large eyes. It is thought that these amphipods were benthic forms. The low occurrences of amphipods in the months when the food was predominantly planktonic may suggest that they may be accidentally taken and not specifically chosen. Isopods were rare in C. flavescens stomachs, planktonic forms being common. A benthic form, taera sp was found in very large quantities in July, together with benthic amphipods. Other non-planktonic food were insects and insect larvae present between April and July with a peak in June. Large quantities of insects were found in the stomachs at this time. * See Appendix

From the food analysis it was concluded that C. flavescens feeds primarily on plankton. It is however not an obligate plankton feeder as the December and July samples demonstrate. In these months the fish changed to benthic food.

## 9. Atherina presbyter

Atherina presbyter is a shoaling fish; the occurrence of this species in the catches in Loch Etive was discontinuous. Relatively large numbers were caught between October-December also in February. None was caught until April but they occurred in large numbers between May and July, disappearing from the catches once again in late summer and autumn. Only one fish was caught in October 1972.

Wheeler (1968) mentions that this species feeds on small crustaceans in general. No previous information was found about its food in the literature.

A total of 334 fishes were examined between October 1971 and July 1972. The results of the stomach analyses are given in Table 26.

The monthly food analysis showed that this species largely feeds on zooplankton, but like Chaparrudo flavescens, it is not entirely a plankton feeder. Planktonic organisms were the primary

food item in fish stomachs in all months samples with the exception of December and July when the fish became a predominantly benthic feeder. Only 1 specimen was caught in October 1972, its stomach contained decapod larvae, calanoid copepods and broken natantia parts indicating planktonic feeding.

Among the planktonic food taken, calanoid copepods had the highest PO and PP values. They were present in considerable quantities in all months examined, except in July; Pseudocalanus sp, Paracalanus sp and Temora sp vere common. Adult Calanus sp seemed to occur more frequently in larger specimens suggesting the possibility of prey size selection in
this species. Harpacticoid copepods were much less common than calanoid copepods. Both planktonic and benthic species were found. Other important components of the planktonic food were cladocerans, cirripedes, polychaete larvae and decapod larvae. Cladocerans occurred in significant quantities in October and also between the months April-June. Cirripedenauplii were especially important in April and May. In December, barnacle cirri were also found in fish stomachs. The greatest percentage of polychaetes were present as planktonic larval forms but In Pebruary some adult polychaetes were found. Most of the decapods were also larvae. Parts of natantia ware recorded in a few instances.

Amphipods were not well represented in Atherina presbyter except in December and especially in July (Fig 9, Table 27). 70\% of the total amount of food consisted of amphipods in July most of which were benthic forms, Corophium sp being especially important. Similarly in December benthic amphipods has a high frequency of occurrence. A large proportion of amphipods found in fish stomachs could not be identified in most months, therefore it is not possible to estimate the relative amounts of benthic and planktonic amphipods in the diet

with any certainty.
The results of the food analysis suggest that Atherina presbyter is basically a zooplankton feeder but is also capable of benthic feeding. Among the benthic food, amphipods, polychaetes, isopods and mysids are taken.
10. Pleuronectes platessa.

The diet of plaice has been widely studied and only a few of the previous references will be mentioned here. Blegvad (1917) found that adult plaice in Danish vaters feed mainly on small bivalves, gastropods, polychaetes and to a lesser extent on crustacea. Young plaice feed on copepods, ostracods, polychaete and amphipods.

Macer (1967) examined the food of young plaice from North Wales, he found that in the diet of born 0 and $I$ group plaice, polychaetes predominate but amphipods (especially Ampelisca sp), lamellibranchs and copepods are also important. Cyclopoids and harpacticoids had a higher frequency of occurrence in younger fish than older fish. Young fish also tended to eat lamellibranch siphons rather than adult molluscs.

Edvards \& Steele (1968) similerly found that 0 group
plaice from Loch Ewe fed on bivalve siphons, amphipods, polychaete, harpacticoids and cumaceans. They noted that the diet of younger fish largely consists of bivalve siphons and polychaete tentacles; as the fish grow older they change to diets of whole polychaetes, amphipods and cumaceans.

De Groot (1973) showed that in the southern North Sea, polychaetes and molluscs were the most important components of the plaice's diet. Younger fish mainly fed on polychaete worms and Macoma Ealtica siphons; as they grow older, crustaceans become an important part of the diet in addition to molluscs.

Thijssen, Lever \& Lever (1974) also examined the food composition of 0 group plaice from a sandy beach. They found polychaetes were the most important food item, folloved by crustaceans.

In Loch Etive a total of 148 specimens were caught and examined throughcut the year. Table 29*shows the monthly sample sizes and food composition. The sample size range for the whole year wes 29-175 mn.

* See Appendix

Table 28. The food composition and the relative importance of various food groups in the diet of P. platessa.

a) Polychaetes
b) Amphipods
c) Molluscs.

polychaetes occurred in fish stomachs in most months, in May, June and July small sabellids and polychaete tentacles had a higher frequency of occurrence than adult polychaetes.

Amphipods also had high PO and PP values in most months except in April and May (Table 29 , Fig 10). Ampelisca sp was the most common amphipod in the diet. Corophium sp and Microprotopus sp also had relatively high frequencies of occurrence. Edwards \& Steele (1968) mention that in Loch Ewe, Microprotopus sp were eaten by dabs (Limanda limanda) but not by plaice. In plaice stomachs from Loch Etive, however, this species was also found to occur.

Molluscs were the third most important food group in the plaice's diet. They consisted mainly of bivalve siphons; gastropods, whole bivalvesbeing occasionally found; chitons were recorded only once.

Harpacticoids became important in the diet in May and July, when the juvenile fish in the samples vere abundant. Like harpacticoids, ostracods, cumaceans, cladocerans vere found more frequently in smaller specimens than in larger fish.

* See appendix

## 11. Platichthys flesus.

Relatively comprehensive data on the food of flounder exists in the literature. Blegvad (1917) found that flounders om Danish waters fed on bivalves, gastropods, polychaetes and crustacea. Among the crustacea, Gammaridae, Idotea sp, Crangon sp were common. Larsen'3 (1935) stomach content analyses showed similar results; he found Idothea sp and Gammarus sp were of major importance in the stomachs of flounders. Mus (1967) investigated the food of flounder in Danish waters; his results agree with those of Larsen and Blegvad.

In Loch Etive 126 specimens were caught and examined, throughout the sampling period. They ranged in size from 37-227 mm.

Amphipods were the most important food item in the diets of flounders from Loch Etive (Table 30, Fig 11). Corophium ap occurred with greatest frequency and constituted the bulk of the amphipods. Gammarids were the second most frequent group.

Polychaetes were consistently present in all months in substantial quantities, forming the second most important food item in the diet (Fig 11). The other importent food categories were molluscs and ispods. Among isopods raera sp

had a high frequepcy of occurrence.
No seasonal trend was apparent in the monthly distribution of occurrence and amounts of the major food types. (Table 31).
12. Pollachius virens.

A relatively large literature exists on the diet of
Pollachius virens. The food of saithe has recently been

* See Appandix
comprehensively covered by Nagabushanam (1965). He mentions that this gadoid has a pelagic phase until they reach a length of 53 mm ; between 53 and 70 mm they become bottom living. Up to 53 mm , saithe feed on calanoid copepods, euphausiid larvae, fish eggs, cladocerans and decapod larvae. In the demersal phase they take amphipods, isopods, mysids and polychaetes. In Loch Etive 149 specimens were caught, varying in length between 23-225 mm. The young fish under 53 mm were caught in May, June and July. Due to the absence or very low numbers of specimens caught in some months, the seasonal variation of the food types has net been treatiod in detail.

The results showed that unlike the food composition of most other fish species examined, no one food categary had an exceptionally high percentage of occurrence. The highest $P O$ value found was for copepods and was only $11 \%$. Other food types which formed relatively large proportions of the total bulk of food were amphipods, decapods and polychaetes.

The saithe from Loch Etive were found to be mixed feeders, taking both planktonic and benthic food. In May, June and September the food was predominantly planktonic. Among the zooplankton taken, calanoid copepods, decapod larvae and

Gobiidae, Indet. Pish, Fish larvae DIGESTED MATTER

PLANT MATTER
cladocerans were especially common; cirripede nauplii and cylopoid copepods occurred to a lesser extent.

Amphipods were most important in the summer and also in autumn, they were not well represented in the winter and were absent in spring. Among amphipods that could be identified, gammarids were of primary importance followed by Corophiun sp and Hyale sp.

All polychaetes recorded were adult; no polychaete larvae was found among the planktonic food. Polychaetes became the most important food group in winter. They were also found in indignificant amount in autumn and summer but
not in spring.
Among the decapods, shrimps were more common than crabs; in the months where planktonic food was taken, decapods consisted of larval forms.

Harpacticoid and cyclopoid copepods and ostracods were only found in smaller specimens caught between May-June. Feeding on planktonic organisms, although commonest in fish less than 49 mm in length, was not restricted to these smaller fish, because the September samples (size range $113-142 \mathrm{~mm}$ ) consisted of fish which had been feeding entirely on planktonic food.

This may serve to demonstrate that planktonic feeding in saithe is not entirely dependent on fish size. Among the plankton eaten, fish lervae was taken by larger fish, perhaps indicating some size selection.
13. Gadus morhue.

The studies on the feeding habits of cod are numerous, although most of them deal with the food of adults.

Nagabushanam (1965) gives a comprehensive list of the food of different sized cod. He found that young cod, up to 48 mm in
length, feed on calanoid copepods and decapod larvae. Demersel fish of 44-370 mm length in shallow waters take mysids, euphausiids, amphipods, polychaete and fish.

In Loch Etive only 36 specimens with a size range of 31-104 mm were collected over the 13 month period. Since the'size of monthly samples were too small to give a realistic indication of the seasonal variation in the type of food the data has been pooled.

Copepoda were the most important food group within the sample size range caught, calanoid copepods being the major component. Other significant food types in the cod's diet were amphipods and decapods. (Table 33).

## 14. Zoarces viviparus.

The diet of the viviparous blenny has been relatively well studied. Blegrad (1917) states that Zoarces viviparus in Danish vaters feeds on bivalves, gastropods and small crustaceans, especially Gammaridae and Idothea sp. Larsen (1935) found that crustaceans, particularly Idothea sp and Leander sp make up the bulk of its food. Furthermore, small gastropods and fish were also taken. Murs (1967) mentions that Zoarces eats gammarids,

molluscs, Nereis sp and young gobies.
181 specimens were caught in Loch Etive. Although the monthly sample sizes were often large the number of fish with empty stomachs was very high throughout the sampling period (see section on the seasonal variation in the quantity of food $p 104$ )for this reason the results have been pooled. (Table 34).

The main food of Zoarces viviparus was amphipods, isopods and crabs. $80 \%$ of the amphipods in fish stomachs were in a broken condition and could not be identified; the relative frequencies of the different species therefore has not been estimated. The proportion of highly digested matter in fish stomachs was higher than in all the other fish species examined.
15. Crenilabus melops.

Blegrad (1917) has found that this species feeds on Idotea sp, Gammaridae, Crangon sp, small molluscs and insect larvae. The young stages feed on copepods.

23 specimens were caught and their stomach contents examined. (Table 35).

Crenilabrus melops from Loch Etive was essentially a crustacean feeder. Amphipods, isopods and ostracods constituted

## Table 34. The food composition and relative importance of

A large percentage of the diet. Among the amphipods that could be identified, Microprotopus sp was most frequent. Noncrustacean food consisted mainly of insect larvae and molluscs.

## 16. Agonus cataphractus

The occurrence of $A$. cataphrachus in the catches was rare. A total of 26 specimens were caught throughout the samplirg period. (Table 36).

A. cataphractus was found to feed solely on crustacea. Two thirds of the total amount of food consisted of amphipods. Caprellids and Microprotopus sp. were the most common forms. Cumaceans were of secondary importance in the diet, although copepods occurred frequently.

## 17. Hyperoplus lanceolatus

Wheeler (1968) mentions that the food of H. lanceolatus consists of copepods, crustacean larvae, euphausiids and fish eggs.

Table 36. The food composition and the relative importance of various food items in the diet of A. cataphractus.

Table 37. The food composition and the relative importance of various food items in the diet of H . lanceolatus.

Fish larvee

The stomach contents of 63 specimens from Loch Etive were examined.

Hyperoplus lanceolatus was a complete plankton Peeder. Calanoid copepods made up the greatest bulk of the food. Temora sp, Pseudocalanus sp vere the most commonly occurring species. Adult Calanus sp and Centropages sp rarely occurred. Cladocerans and decapod larvae were also present in large numbers. (Table 37).

## 18. Nerophis lumbriciformis

Wheeler (1968) gives the food of the adults of this species as larval and saall crustaceans and larva? fishes. The diet of this species has not been systematically studied. In Loch Etive 27 specimens were caught throughout the sampling period and stomach contents examined. (Table 38).

The food of this species in Loch Etive thus consisted mainly of ostracods, harpacticoids, amphipods and isopods.
19. Syngnathus $\mathbf{s p}$

Two species of pipe fish was found in Loch Etive, Syngnathus rostellatus and Syngnethus acus. Some difficulty was experienced

Table 38. The food composition and the relative importance of various food groups in the diet of Nerophis lumbriciformis.

$33^{\text { }}$
in distinguishing them, especially between the younger members of two species. In order to avoid any errors they were grouped as Syngnathus sp.

Wheeler (1968) lists the food of Syngnathus acus as small amphipods, isopods, small shrimps and crabs. Syngnathus rostellatus feeds on mysids, copepods and young decapods but take Amphipods and Isopods in lesser quantities.

21 specimens of Syngnathus were caught. The main food of this species was found to be mysids, harpacticoid copepods, amphipods. Decapod larvae, zoeae, ostracods and cumaceans were also frequent. Calanoid copepods, shrimps, isopods and cladocera occurred to a lesser extent. A well defined relationship between the fish size and prey size was apparent. Shrimps, mysids, amphipods occurred in the stomachs of lerger specimens, whereas copepods, ostracods were common in smaller members. Among the amphipods members of the family Caprellidae were of frequent occurrence.
20. Anguilla anguilla.

Larsen (1935) found that the food of Anguilla anguilla consisted mainly of crustaceans among which Leander sp, Idotea sp
and Gamarids were especially important.
Most individuals of this species were caught at Dail, the area with the lowest salinity of the three stations sampled. 17 specimens were caught and examined.

Arphipods, insect larvae and isopods were found to occur most frequently in the stomachs. Polychaetes were occasionally taken. Among the amphipods, the families Gammaridae and Corophidae were common.
21. Chirolophis Ascanii.

15 specimens were caught and examined in Loch Etive. This species is essentially a polychaete feeder, sabellid tentacles were very frequent in fish stomachs. Small bivalves and gastropods vere occasional.

## 22. Salmo trutta

It had been mentioned in Table 1 that Salmo trutta, although a member of the inshore fish community, was not included in the analyses as its biology was being studied by another worker at the time of sampling, Pemberton (1975, in press). He found that crustaceans were the most prominent food component, followed by
insects and fish. Amng crustaceans, amphipods were nariicularly important. The food composition $1 \mathrm{sic}^{+}$of S. trutta shows that the majority of prey species in its diet, excluding fish, are common to several inshore fish covered in the present investigation. The extent to which each food group was taken by S. trutta was not worked out in detail; but the frequency of occurrence values for its main food components nevertheless suggest that the degree of utilization of different types of food are different from other fish (Crustaceans 43\%, insects $31.1 \%$, fish $30.6 \%$ ). Thus the feeding habits of S. trutta appear to be similar to the rest of fish community examined, namely it utilizes approximately the same sources of food but to a different extent.

It is interesting to note that among the fish prey of $\mathrm{S}_{\mathrm{o}}$ trutta. ten of the species investigated here are listed, which suggests that S. trutta is a major predator of inshore fish and plays an important role in the economy of the fish community.

The seasonal changes in the amount of food eaten by each species was investigated by calculating a fullness index (F.I.) for each month as the mean number of points allotted/stomach for those species which had a relatively large sample size. The fullness index only gives an overall picture of the seasonal trend but does not show the variation of fullness in each monthly sample. To demonstrate this variation the frequency of stomachs that were empty, trace full, $\frac{1}{4}$ full, $\frac{1}{2}$ full and full were also calculated.

For this purpose the stomachs were clissified from empty to full as follows:

## No. points allotted

$0-0.5$
0.6-3
$4-7$
$8-12$
13-17
$18-20+$

Fullness category of stomach
Empty
Trace
1 full
$\frac{1}{2}$ full
4 full
full

A clear seasonal pattern in feeding intensity was evident in most of the species examined. Since this was similar for all of them, only Spinachia is treated in detail in this respect. For the remainder general comments will be sufficient.

## 1) Spinachia spinachia

Fig 12a shows that the fullness index decreased slightly from October 1971 onwards and remained low during the months December, January and Pebruary, a small increase was found in March but this was not continued into April where the amount of food in fish stomachs was as low as January. Prom April to June the increase in the F.I. was quite marked; it decreased slightly in July, but in August was comparable to June values. The amount of food in the stomachs remained quite high in September and began to decline again in October.

Despite the slight variation it is clear from Pig 12a that the fluctuations in the percentage of empty stomachs and the F.I. show an opposite pattern. The percentage of empty stomachs was highest in the winter months whereas the fullness index was highest between May and September.

The number of fishes showing the different degrees of stomach fullness were also examined. Table $39^{\circ}$ gives the number of stomach's in different fulness levels per month. It will be seen from Table 39 that completely empty and full

stomachs were present in almost every month, but their proportion in the sumer and winter months was markedly different.

In order to follow in more detail the changes that took place in different fullness categorics in successive months, it was necessary to calculate how much the different levels of fullness observed in one month differed from those observed in the following months. A statistical comparison of monthly fullness categories was therefore performed.

As mentioned earlier, errors in fullness estimation may have occurred from month to month, e.g., a stomach classified as $\frac{3}{4}$ full in one month may be classified as full the next month. Although errors of this sort are not likely to be great, an attempt was made to reduce their effect on the pattern of seasonal variation by grouping those categories most likely to be confused. Empty and trace categories were combined as a low level group and 3 full and full as a high level group. These combinations (Group 1 in Table 39) were considered to reduce the errors of judgement, particularly in the high level group.

A second combination was made by grouping all stomachs between empty and $\frac{1}{4}$ full ( $0-7$ points) to give a lov food level
stomachs were present in almost every month, but their proportion in the summer and winter months was markedly different.

In order to follow in more detail the changes that took place in different fullness categories in successive months, it was necessary to calculate how much the different levels of fullness observed in one month differed from those observed in the following months. A statistical comparison of monthly fullness categories was therefore performed.

As mentioned earlier, errors in fullness estimation may have occurred from month to month, e.g., a stomach classified as $\frac{3}{4}$ full in one month may be classified as full the next month. Although errors of this sort are not likely to be great, an attempt was made to reduce their effect on the pattern of seasonal Variation by grouping those categories most likely to be confused. Empty and trace categories were combined as a low level group and $\frac{3}{4}$ full and full as a high level group. These combinations (Group 1 in Table 39) were considered to reduce the errors of judgement, particularly in the high level group.

A second combination was made by grouping all stomachs between empty and $\frac{1}{4}$ full ( $0-7$ points) to give a low food level
class and $\frac{1}{2}$ full to full ( $8-20$ points) to give a high food level class. The second grouping included all the fishes in a months sample and would further decrease the possible errors introduced by inaccurate estimation of fullness categories (Group 2 in Table 39).

Monthly differences in fullness in both groups were compared by a $x^{2}$ test after applying Yates correction. The results for Groups 1 and 2 are given in Tables 40 and 41 respectively.

From the results given in Table 40 the following conclusions can be made:

1. Consecutive months are rarely different except November and December; April and May and August and September. Therefore, the increase or decrease in fullness levels is gradual.
2. Greatest differences (i.e., highest significance levels) occur when summer and winter months are compared.

Table 41 demonstrates essentially the same points except that the decrease from November to December become more gradual and Pebruary and March appear more markedly different from the low food level months, December, January and April.

Both of the comparisons showed that in April the fishes

had very small amounts of food in their stomachs. Food measures for this month were as low as January and December. This could not be explained by small sample size or a change that might have taken place in the type of food consumed (see Table 11) or a sudden change in temperature as no such drop in temperature was recorded. The food composition was not significantly different from the previous or following months. Most adults had very mature gonads in this month but the presence of full intestines showed that feeding had not ceased. The high number of stomachs either empty or with trace amount of food is thought to be a result of highly digested state of food in the guts.

The percentage of stomachs corresponding to the high and low level fullness categories in Group 1 and Group 2 are also given in Table 39.

It is clear from the seasonal variation in the percentages of stomachs in Group 1 and Group 2 that percentages follow the same trend as the $\chi^{2}$ values given in Table 40 and 41. They show the progressive increase in the number of empty stomachs (Group 1, column a) and in the number of stomachs with low amounts of food (Group 2, column a) from October to January. They both
show the January minimum, the July-August maximum and that autumn and spring values were intermediate between winter and summer. In both cases the inverse relationship between summer and winter stands out quite sharply.

It can be concluded, therefore the although statistical comparison of high and low food levels between months gives a more detailed account of the changes that take place, the consideration of percentages is probably sufficient to follow the general pattern and statistical comparisons of this sort for the other species were not made.

## 2) Gasterosteus aculeatus

The seasonal pattern of variation in feeding intensity of this species (Fig 12b, Table 42*) was similar to that of Spinachia except that the increase in feeding appeared to start somewhat earlier and remained more or less constant for most of the spring and summer.

## 3) Myoxocephalus scorpius

Here again the general trend of high feeding intensity in summer and low intensity in winter was apparent (Fig 12c, Table 43*), but this species seems to have a shorter period of low level feeding (Dec-Jan) than most others.
4) Taurulus bubalis

The number of individuals of this species caught in most montins vas usually small. The variation inherent in small samples

[^3]inevitabley affects the estimation of seasonal trends in the amount of food consumed (Table 44*) but in spite of this a seasonal pattern was nevertheless apparent.

## 5) Pholis gunnellus

The quantity of food consumed by $P_{\text {. gunnellus also showed a very }}$ clear seasonal trend. (Fig 12e, Table 45*).

The winter decline in the feeding of $P$. gunnellus is strongly influenced by the onset of the spawning season which takes place in January and Pebruary (Qasim 1957, Wheeler 1969). Wheeler statea that in winter, most females and some males guarding eggs cease feeding. Smith (1887) states that the breeding season in this species lasts from Pebruary to April. Quasim (1957) found that in North Wales feeding intensity reached a high level in April and May and remained so until October. In Loch Etive the fish stomachs still had very small amounts of food in April. It is apparent, bowever, that the general trend shown by fish in Loch Etive is comparable to that found by Qasim in North Valas

## 6) Atherina presbyter

Although no samples were obtained for August, September, October 1972, the pattern of monthly variation in the F.I. of this species appeared to be slightly different from the fishes considered • previously. (Fig 12f, Table 46*).
$80 \%$ of stomachs were $\{$ full or completely full in October 1971 which was similar to the summer maximum found for the other species

[^4]previously discussed. No empty, trace full or $\frac{1}{4}$ full stomachs were found and the F.I. for the month was very high (17).

Spawning in these fishes takes place in mid-summer (Wheeler 1968) and this may have a depressing effect on feeding. Atherina presbyter is a shoaling fish feeding on plankton; low amounts of food found in July and very high amounts observed in October, November could also be due to patchiness of the food.

## 7) Pomatoschistus minutus

With the exception of October 1971 and November the quantity of food in the stomach of $P$. minutus appeared to change seasonally in a consistent pattern (Fig 12g, Table 47*). The F.I. decreased sharply in December and was very low from January to March. It then began to rise in April, increasing steadily until a peak was reached in August, declining again in September and October 1972.

As mentioned earlier, most monthly samples were collected at low tide. Healey (1970) found that feeding activity had a tidal rhythm, most feeding taking place at high tide. If this feeding rhythm is also present in Loch Etive fish, then most -
monthly fullness index values are probably under-estimates of the actual amounts present.

Zoarces viviparus
Zoarces viviparus stomachs in Loch Etive were characterized by very low levels of food found throughout the year (Fig 12h).

As will be apparent from Table 48*, the percentage of empty and trace full stomachs was particularly high in the winter. Although an increase in feeding intensity occurred in April, it still remained relatively low during the summer. There was no sample for August. Even in June and July when the largest amounts of food were found in the stomachs, $55 \%$ of stomachs were empty to trace full.

The high percentage of empty stomachs in the winter could be explained by cessation of feeding during the breeding season. The presence of low food levels during the warmer months auggesta, however, that some other factor apart from the temperature and breeding season may be responsible for these values, possibly a strong tidal or nocturnal feeding rhythm. If the fishes fed mostly at high tide or at night, a large percentage of empty stomachs would have been found at low tide and during the day,

* See Appendix
when most of the fishes were caught. The fact that in all months some food was found in the intestines may support this view.

9) Chaparrudo flavescens

The seasonal change in the stomach contents of $C$. flavescens does not show much deviation from the general pattern of high levels of food in the summer and low levels in the winter. (Fig 12i, Table 49*).

It is worth mentioning that in November 1972 two samples collected on different days showed much variation in fullness. One sample had nearly all empty to $\frac{1}{4}$ full stomachs whereas in the other sample $80 \%$ of the stomachs were $\frac{3}{4}$ full to completely full, similar to those values found in the summer months. Chaparrudo flavescens is a shoaling fish and the food in November consisted of zooplankton. It is possible that the sample with

* See Appendix

#### Abstract

full stomachs were caught immediately after the shoal had fed on a plankton patch. Patchy feeding could be a potential source of error in the months where the greatest percentage of food was planktonic but the overall seasonal pattern was consistent.

10-14). Pleuronectes platessa, Platichthys Plesus, Pomatoschistus microps, Gadus morrhua, Pollachius virens.

Most of the monthly samples for these five species were very small, the samples for cod being particularly scanty. Tablea 50-54* show, however, that following the general trend of all other species stomach contents were low during winter months and high in the summer.

The figures in the tables suggest that feeding intensity began to rise in April in P. platessa, P. microps, P. virens and in May in P. Plesus.

## SUMMARY AND DISCUSSION OP VARLATIONS IN FEEDING INTENSITT

In most of the species examined a well marked seasonal variation in the feeding intensity was found.

The general pattern, as demonstrated for example by Pig 12

* See Appendix
and Tables 39-54 was the presence of low levels of food in the winter and high levels in the summer. The trend was apparent even in those species where the monthly samples were relatively small.

The low food content of fish stomachs in the vinter appears to be a common phenomenon and has been demonstrated in many different species by various workers. Ball (1961) found similar results in trout in a Welsh lake, Skazkina and Kostyuchenko (1968) in the Azov goby, Tyler (1973) in the demersal fishes of Passamaquody Bay, Lande (1973) in plaice of Borgenfjorden and Hunt and Jones (1972) in brown trout.

High food levels in the summer seems to be correlated with increasing daylength and more significantly with increasing temperature. Ball (1961) found a close correlation between the food quantities and temperature and daylength in brown trout. Hathaway (1927) demonstrated experimentally in Eupomotus gibbosus (L), Lepomis incisor. Micropterus salmoides that food intake increases three fold when the temperature is raised from 10 to $20^{\circ} \mathrm{C}$. He found that moderate changes in illumination produced no perceptible effect on food consumption. Skazkina and Kostyuchenko (1968), and Tyler (1973) also found correlations
between increasing quantities of food in stomachs and a rise in temperature. Swift (1955) maintains that the activity and appetite of trout increases with increasing temperature and daylength resulting in an increased food level. Internal factors such as the onset of the breeding season, as well as environmental factors, undoubtedly play an important role in the changes that occur in feeding intensity.

## THE RELATIONSHIP BETWEEN FISH SIZE AND PREI SIZE

The results of the food anslyses suggested that the size of the prey found in a fishes stomach was often related to its body size. In some fishes there was evidence for the existence of a clearly defined size-related feeding heterogeneity (Tyler, 1972) i.e., the food changes from one type to another over a certain range of body lengths. These changes were most ovious in those fishes which fishes which had a large size range. Por example, in $M_{\text {. scorpius }}$ where the length range was between 24-230 mm and in S. spinachia where it was between $35-134 \mathrm{~mm}$. The differences were more obscure in species which did not reach a large size as in P. minutus which had a size range of $\mathbf{3 1 - 7 8} \mathrm{mm}$ over a year.

This relationship between prey size and body size will be discussed for individual species below.

1) S. spinachia

In S. spinachia harpacticoid copepods increased in importance in the diet of those months when juvenile fishes began to appear in the samples, reaching their peak of importance in July when the majority of fishes were very young; the range of total lengths for July being between 35-57 min. The seasonal abundance of ostracods was similar to harpacticoids. Their overall importance in the diet was low except in very small fishes. Ostracods, harpacticoids and calanoid copepods were important in the diets of fish $<70 \mathrm{~mm}$ total length. Insect larvae, although occurring throughout the size range, were similarly found in largest quantities in fish below 70 mm .

Amphipods as a group had comparable frequency of occurrence values throughout the whole fish size range examined, but the actual size of amphipods in the fishes stomachs clearly varied with the predator size. Fig 13 shows the relationship found between body length of amphipods and that of S. spinachia. The correlations between the mean maximum amphipod length (line $C$ in Fig 13), mean amphipod length (line $B$ in Fig 13) and fish size

Fig. 13. The relationship between the size of prey (emphipods) and the body length of S. spinachia.

Line $a_{1}=$ mean minimum prey size, $r=0.718$
Line $b=$ mean mean prey size $\quad r=0.979$
Line $c=$ mean maximum prey size, $r=0.985$.

were highly significant ( p 0.001 ). The mean minimum amphipod size also increased with increasing fish size (line A, in Fig 13), but the relationship was not as pronounced as in the case of mean maximum amphipod length and mean amphipod length $(p=0.05)$. If line $A$, in Fig 13 is examined, it will be seen that mean minimum prey size remained relatively unchanged over the greater part of the predator size range, between $50-110 \mathrm{~mm}$, a considerable increase being noticeable only in the 120 mm predator size group. When the mean amphipod length for this size group was excluded from the calculations, the correlation between the mean minimum amphipod length and predator length was no longer significant. (Line $A_{2}$, Pig 13). This suggested that the observed relationship between the mean amphipod length and fish size was mainly due to an increase in maximum size of prey taken rather than an increase in minimum size, the slopes of the lines $A_{1}, B$ and $C$ further demonstrating that the sharpest increase was observed in the mean maximum prey size and the least increase in mean minimum prey size. The size range of prey taken thus increases greatly as the fish size increases.

Although, as mentioned above, the occurrence of amphipods as a group did not change greatly throughout the fish size range,
the importance of different species did vary with fish size. The larger amphipods, such as gamarids increased in importance as the fish size increased, and conversely the smaller bodied amphipods such as Nototropis sp and especially Microprotopus sp decreased. Table 55 shows the percentage quantities of common species of amphipods taken by different size groups of S. spinachia.

Table 55. Relative importance of different types of amphipods in different size groups of S. spinachia. expressed as a percentage of the total number of points gained
by each species of family throughout the size range.

| Amphipod type | Pish body length (cm) |  |  |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 |
| Gammaridae |  | - | - | 7 | 8 | 6 | 12 | 14 | 13 | 19 | 21 |
| Corophium sp |  | - | - | - | - | 9 | 14 | 16 | 11 | 35 | 15 |
| Caprellidae |  | - | - | 15 | - | 45 | 13 | 2 | 16 | 9 | - |
| Hyale sp |  | - | - | 26 | 32 | 14 | 9 | 4 | 8 | 5 | 2 |
| Nototropis sp |  | - | 21 | 35 | 23 | 11 | 4 | 1 | 3 | 2 | - |
| Microprotopus | sp | 19 | 26 | 22 | 17 | 10 | 3 | 1 | 1 | - | 1 |

Like gammarids, mysids could also not be found in fish stomachs in July, although they were plentiful in the environment. When the occurrences of mysids in different fish size groups were calculated, it was found that feeding on mysids begins to be important above 70 mm total length, although they also occur occasionally in the 50 mm and 60 mm size groups. The lack of mysids in the fish stomachs in July was probably a result of the fishes being smaller (mean fish length in July was 42 mm ) than the lowest total length at which mysid feeding begins to be important.

Among the isopods Idotea sp occurred in significant quantities above 90 mm total length. Smaller bodied Taera sp occurred over a wider size range.

Fig. 14 sumarises the relationship observed between food types and fish size.
2) Myoxocephalus scorpius

As suggested earlier, the amount of amphipods in the stomachs of M. scorpius was dependent on the total length of the fishes in the sample. Amphipods became important in June and July when juveniles appeared in the samples. They formed $98 \%$ of the food of the fishes with a total length between 27 and 50 mm .

Fig 14. The relationship between the fish length and type of food in S. spinachia.
$\begin{array}{llllllllllll}\text { Fish length }(\mathrm{cm}) & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 & 13\end{array}$

Most commonly occurring prey

Amphipods

There was also a secondary division of amphipods which wes related to the total fish length. In the $50+$ min size group, the commonest amphipods were gammarids. The PO and PP values for Ampelisca sp, Corophium sp, Nototropis sp and Microprotopus sp decreased in that order as the fish size increased from 20 mm to 50 mm . Lower proportions of smaller bodied amphipods were taken as the fish size progressively increased. Other smaller bodied
prey, ostracods and harpacticoids were only important in the diet of the smallest fish with total lengths between $20-30 \mathrm{~mm}$.

In the July samples most fish were juveniles. The food division within the fish size groups followed the same pattern as in June, that is, the largest fish fed primarly on large Carcinus. In the diets of intermediate sized fish, smaller crabs were important as well as shrimps and in the $9-10 \mathrm{~cm}$ group large amphipods, gammarids and Ampelisca sp began to gain importance. P0 and PP values for both increased as the fish size progressively decreased while the proportion of smaller bodied amphipods Nototropis sp (mean total length, $\overline{\mathrm{TL}}=3 \mathrm{~mm})$ Microprotopus $\mathrm{sp}(\overline{\mathrm{TL}}=2 \mathrm{~mm})$; Monoculopsis $\mathbf{s p}$ $(\overline{\mathrm{TL}}=2 \mathrm{~mm})$ decreased with increasing fish size. The values for harpacticoids were similar to those of smaller amphipods. In August, adult M. scorpius were found once again to be feeding predominantly on shore crabs. Crabs or shrimps occurred extremely rarely in the fishes with a total length below or equal to 60 mm . Fish as prey only occurred in M. scorpius larger than 120 mm .

Fig 15 sumarises the described selection in M. scorpius.

Fig 15. The relationship between fish size and the type of prey in M. scorpius.

It was concluded that there was a well defined size-related feeding heterogeneity in $M_{0}$ scorpius as the type and proportion of the food taken altered with the size of fish.
3) Taurulus bubalis.

On the whole, sample sizes and the size range of fish in the samples were smaller in T. bubalis than in M. scorpius. The size range of $T$. bubalis was $\mathbf{3 8 - 1 6 8} \mathrm{mm}$ whereas in M. scorpius it was 24-230 mm. When similarly sized individuals were compared
however, T. bubalis seemed to prefer smaller sized food than M. scorpius. This may explain the considerable difference found in the principal food types between the two species. As stated earlier, bulky crabs and shrimps form the main food of M. scorpius whereas amphipods, polychaetes and isopods are more important to $T$. bubalis. Other differences in the diet were probably related to habitat preferences of the fishes.

In the July samples, the number of juveniles of T. bubalis like those of M. scorpius, were large. Once again it appeared that among juveniles, smaller amphipods such as Microprotopus sp; (mean total length in juveniles spmachs $=1.5 \mathrm{~mm}$ ); Urothoe $\mathbf{s p}$ ( $\overline{\mathrm{TL}}=2 \mathrm{~mm}$ ); Bathymedon $\mathrm{sp}(\overline{\mathrm{TL}}=2 \mathrm{~mm})$ were more frequent in juveniles. The small sample sizes precluded, however, any detailed size analysis. Larger bodied Isopods such as Idothea sp were found in higher proportions in larger juveniles. In smaller fish, only small sized taera sp were found.

Although selection of smaller prey by smaller fish was apparent in most fishes, size-related feeding heterogeneity was not always well defined. In Pomatoschistus minutus for example, the food of the fishes at both ends of the size range were markedly different. At one end, 7 cm fish were capable of taking
shrimps, large proportions of Ampelisca sp and polychaetes. At the other end, 3 cm Pish took more harpacticoids, ostracods and smaller amphipods, but the boundaries of the fish size groups where the changes from one type of food to another occurred were not clear. Both small and large food organisms appeared to be finally taken by all fish size groups between 3 cm and 7 cm . It was concluded, therefore, that in P. minutus size related food heterogeneity was not clearly defined.

Size dependent food selection was also clear in juvenile G. morhua, P. virens, P. platessa, P. flesus, P. gunnellus and Syngnathus sp, but less clear in the other species examined. Size selection was also apprent in plankton feeders; where in smaller members, small bodied species such as Psoudocalanus, Temora, Paracalanus and juvenile Calanus wore abundant and larger prey such as adult Calanus, Centrapages sp were rare. The proportion of the latter were much higher in the larger specimens. Also, in A. presbyter fish larvae were found only in the very large specimens and did not occur in others.

Most studies of the feading habits of fishes imply that the fishes are generalists, emphasising the variety of prey found in their diets. Much of the earlier work on the fish communities was carried out in freshwater systems.

Hartley (1940) analysed the food of coarse fish in English waters and came to the conclusion that there were wide interspecific similarities among the fish concerned. Later Frost (1946) examined the food relationships of freshwater fish in Windermere; she found that the food requirements of most fishes are closely related and often overlap. In 1947 Hartley investigated the feeding habits of estuarine fishes. He reached the conclusion that there was some division of food among the fishes and classified them into four groups. 1. Fish without competitors, 2. Fish whose food consisted of organisms for which there was little competition, 3. Fish which fed on the commonest organisms but which had a wide choice of foods, 4. Fish which had many competitors for the bulk of their food. In 1948 he once again examined the feeding relationships in a
community of Preshwater fishes in Westmorland, showing that no two species had identical feeding habits and concluding that there was much competition between the fish.

More recently, Keast (1965) examined resource subdivision among the freshwater fish community in an Ontario Lake. He showed that the diets of fish overlapped only when food sources were abundant, otherwise there was a marked tendency for the fish to concentrate on different food organisms. He also found the competition between different size groups within the fish species was limited.

Zaret and Rand (1971) examined the food of nine freshwater fishes in a tropical stream in Panama. Their results were similar to those of Keast in that dietary overlaps were minimal when the food was least abundant, in this case, in the dry season.

Food resource partitioning among marine fish has been studied by several authors. Skalkin (1959) examined the flatfishes of a Northern Pacific lacality and showed that related species had different predation tendencies in terms of their major prey. Richards (1963) investigated the food of juvenile fish populations of Long Island Sound, and found that different species
of fish had different feeding habits. Nagabushanam (1965)
examined the food of gadoids from the Isle of Man; he
similarly found that the food resources were divided among the related species. Gibson (1968) investigated the food and feeding relationships of littoral fish in the Banyuls region. He found that the majority of fish species examined were carnivores feeding mainly on crustaceans. In 1972 he looked at the feeding relationships of intertidal fish on the Atlantic coast of Prance. He once again found that crustaceans, especially amphipods form a large part of the food in most species, although the importance of othrr groups varies considerably. Tyler (1972) found that marine demersal fishes showed relatively little overlap in their diets and that there was a division of food resources among the fishes.

In this section, the diets of all the species will be compared and an attempt will be made to assess the feeding niche each fills in the community as a whole.

## COMPARISON OF MODES OF FEEDING.

The food analyses of the twenty two species showed that all species examined fed almost exclusively on animal food. Algae formed a very small fraction of the diet in most species and it is concluded that it was probably taken accidentally. The fish may be grouped inte three categories according to their feeding habits.

1) Plankton Feeders

Atherina presbyter, Chaparruda flavescens and Hyperoplus lanceloatus vere predominantly plankton feeders. Chaparrudo flavescens took plankton in October, November, January, Pebruary, April, May, June but in December took a large proportion of benthic food in addition to plankton and in July fed completely on benthos. Atherine presbyter similarly took 200plankton in most months, but like Chaparrudo flavescens its food became predominantly benthic in December and July. Whether the observed change from planktonic food to benthos in the same two months in these fish was caused by a common environmental factor or was coincidental is not known. It is
significant, however, in demonstrating that these plankton feeders are capable of benthic feeding under certain conditions.
2) Mixed Feeders.
G. aculeatus, though primarily a benthic feeder, took large proportions of planktonic food in spring, late summer, and especially in autumn. In September and October zooplankton became its primary food. It is likely that the small size of zooplankton and their increased abundance rendered them a suitable food at this time. Plankton feeding, however, was not as pronounced in spring. Similarly, juvenile Gadus morhua and Pollachius virens took planktonic food in some months. In Pollachius virens the food was predominantly planktonic in May, June and September. Gadus morhua took higher amounts of plankton than Pollachius virens, mostly in spring and early summer. There was no sample in autumn for this fish. In both fishes plankton feeding may thus be a reflection of increased zooplankton abundance following the spring and autunn blooms, as well as being defendent on the size of the fishes in the samples. Nagabushanam (1965) mentions that plankton feeding in gadoids occurs in juveniles in their pelagic phase and continues until they reach
a length of 53 mm . In September, however, plankton was found to be the chief food of larger P. virens with a size range of 113-142 mm, which showed that plankton feeding may not entirely depend on Pish size.

## 3) Benthos Feeders

The majority of the species examined belong to this category. Occasional planktonic food, especially calanoid copepods was taken in small quantities by otherwise essentially benthic feeders such as P. minutus, P. microps, P. gunnellus, A. cataphractus and S. spinachia. Generally the occurrence of planktonic food did not show a seasonal pattern but was associated more with the occurrence of smaller fish in the samples. This probably means only that small fish took calanoid copepods because they were suitably, sized and occurred in shallow water around algae, rather than a distinct change of feeding habit. In September, however, a group of adult S. spinachia, which are true benthic feeders, were found to have been feeding on zooplankton. In this case zooplankton feeding was clearly not associated with small fish size. No planktonic food was ever found in the stomachs of M. scorpius
and T. bubalis reflecting their truly demersal mode of life. Insects of aquatic and terrestrial origin occurred in the diets of several species, although their proportions in the diet were often small. They were relatively well represented in the diet of $G$. aculeatus and also occurred to a much smaller extent in S. spinachia, P. gunnellus, P. minulus, P. microps, P. platessa, P. flesus, Z. viviparus and C. melops. Their occurrence in fish stomachs was irregular and often restricted to summer and autumn months. Although they never became an important part of the diet, they demonstrated the flexibility in the feeding habits of these species.

Fish were only found in any numbers in the diets of M. scorpius, T. bubalis, but were also present to e lesser extent in G. morhua, P. virens and P. plesus.

The examination of the food of different fish hence showed that although majority of fish found in the shallow waters of Loch Etive were essentially benthos feeders, a whole range of types exist whose feeding habits range from complete plankton feeding to complete bottom feeding.

Among the 21 fish species examined, 27 major food groups (amphipods, isopods etc.) and 115 species were identified. The food composition lists for 18 species given earlier show that some food types are more extensively utilized than others. Crustaceans were by far the most common food in every fish species examined. This is similar to Gibson's $(1968,1971)$ results where he found crustaceans were the main food of both littoral fish of Banyuls region and intertidal fish of the Atlantic coast of France.

In Loch Etive the lowest values for crustacea were found in P. platessa, P. flesus and T. bubalis, although even there they made up from 49 to $62 \%$ of the total amount of food consuned. Values for crustacea as high as $91 \%$ and $93 \%$ were found in S. spinachia and H. lanceolatus, and A. cataphractus fed solely on crustacean food. The proportion of different major groups of crustacea showed, however, much variation between species and will be more fully discussed later.

Non-crustacean food which was relatively important belonged to the groups Polychaeta, Mollusca and Insecta. The group

Pisces, represented as fish, fish larvse and fish eggs was also not uncommon. Other food groups such as Nemertini, Hydrozoa, Chaetognatha, Ophiuroidea, Actinaria, and Rotifera were rare, occurring in three or fewer fish species.

In order to compare the diets of different species in more detail, the fish and the major food groups have been arranged as a partition plot in Table 56, following Tyler's (1972) method. The food groups which were considered to be most important in the diet of any one species were taken as those which had PO and/or PP values equal to or greater than $10 \%$.

In Table 56 predators are arranged so that those which show the greatest similarity in their major food groups are adjacent to one another. The percentage overlap, or reoccurrence of food groups in more than one predator species, is calculated ty the total number of reoccurrences of prey groups among predators divided by the total number of possible reoccurrences in the partition plot. One reoccurrence means that a prey group occurs in two predator species. The total number of possible reoccurences is calculated as the number had a Po and/or PP value equal to or greater than $10 \%$.

of fish species minus one, multiplied by the number of major prey groups. In the present investigations, the number of reoccurrences between major food groups were 60 , and the total possible number of reoccurrences 255 , giving a percentage reoccurrence value of $23.5 \%$. Table 56 shows at a glance that although the same food groups occur repeatedly in different fish species, when the overall distribution of these major food groups is compared the apparent similarity of diets is greatly reduced, suggesting a tendency for the food resources to be segregated.

The number of major food groups eaten by each species varied between 2 and 5 with a mean value of 3 , showing that most fishes depended on relatively few food groups as their major food. It must be remembered that in the partition plot, food groups, instead of actual prey species are used and this grouping tends to reduce the differences between the predators' diet and to increase similarity. Regardless of this fact, Table 56 shows that, except for $P$. minutus and P. microps, no two species had exactly the same distribution of major food groups. This indicates that, even using this relatively crude comparison, the diets of these fishes are sufficiently different
to prevent masking by the grouping of prey species. Judged by this method, both P. minutus and P. microps appeared to eat the same major food groups; namely amphipods and polychaetes. When the proportion of different amphipods species in both fishes are compared however, some differences become apparent. (See Tables 20 and 22).

Using partition plots to compare the similarity of diets of fishes Tyler (1972) found the percentage of reoccurrence of prey species was $24 \%$ in the winter and $16 \%$ in the summer. He concluded from his results that the fish were specialized predators in terms of their major preys. He also worked out partition plots from Nagabushanam's (1965) data on the food of gadoids and Skalkin's (1959) on the food of pleuronectids. He found only $10 \%$ at possible reoccurrences of principal prey among the pleuronectids and $15 \%$ in the gadoids. The results of the present study are thus comparable with their findings.

The significance of crustacean food in the fishes diet is also apparent from Table 56 as 49 out of the 60 major food groups belonged to crustacea. Among all crustacean, amphipods vere the most important group. They occurred in all fishes with the exception of H. lanceolatus and were a major food
group in all except Chaparrudo flavescens. The lowest value was found in Atherina presbyter where they made up only $10 \%$ of the total amount of food and consisted of both benthic and planktonic forms. In all other fishes they were present as benthic emphipods. $P O$ and PP values were also relatively low in G. aculeatus, P. virens, G. morhua and N. lumbriciformis. The importance of amphipods in the diet of M. scorpius is also low but is masked in the overall food composition of the fish by the very high occurrence of amphipods in the large June and July samples. If the samples of these two months are excluded, amphipods make up only $10 \%$ of the total food in the remaining months.

There were also differences in the relative importance of different species of amphipods in different fishes. 22 species of amphipods were found to occur in 17 fish species but the types which were extensively utilized by the most fish were relatively low. The most commonly occurring amphipods were Gamarids, Corophium sp, Microprotopus sp, Nototropis sp, Ampelisca sp and the family Caprellidae. Amphithoe sp, Hyele sp were also found to occur frequently. Other species listed had occurrences common to 4 or fewer fish species.

Gammarids ware often of primary importance in the diets; especially in S. spinachia, M. scorpius, T. bubalis, P. gunnelliss, $P$. virens and to a lesser extent in G. aculeatus, P. flesus and G. morhua. Corophium sp was most important in P. flesus. G. aculeatus and P. microps, but also made up $10-24 \%$ of all amphipods in T. bubalis, G. virens, P. minutus, G. morhua, N. scorpius and P. platessa. Hyale sp was relatively important in G. virens, G. morhua and S. spinachia. Microprotopus sp, though common to most fish species and having a relatively high frequency of occurrence, usually made up only a very small proportion of the amphipods, except in plaice, P. gunnellus, P. minutus and P. microps. It gained primary iaportance only in C. melops and A. cataphractus. Caprellids similarly occurred in most fishes but in relatively small amounts except in A. cataphractus, C. melops and to a lesser extent in P. gunnellus. Ampelisca sp made up $56 \%$ of all amphipods in. P. platessa, $38 \%$ in P. minutus, $23 \%$ in M. scorpius and $20 \%$ in G. morhue but occurred in much smaller amounts in other Pish.

If the relative proportions of different types of amphipods in different fish are examined, two generalisations
can be made:

1. The number of different species of amphipods are large, but the ones which are extensively utilized by the majority of fish are relatively few; different fish take mostly similar types.
2. Although the same few species are repeatedly taken by different fish, the proportion of the different species in the diet of each predator is significantly different.

The second point above is clearly demonstrated when the relative proportions of different amphipod species are compared between predator species. The degree of overlap in terms of amphipods between fish species was calculated using the overlap measure of Morisita (1959) as modified by Horn (1966) and later by Zaret and Rand (1970). The similarity coefficeint ( $C_{\lambda}$ ) varies from 0 when the samples are completely distinct (containing no amphipod species in common) to 1 when the samples are identical with respect to the proportion of amphipods.

For these calculations the percentage point values for each amphipod species in each fish diet were used. They were first converted to the actual proportion of the total amount of food in a fish diet. The similarity coefficient is calculated from
the following formula:

$$
c \lambda=\frac{2 \sum_{i=1}^{S} X_{i} Y_{i}}{\sum_{i=1}^{S} X_{i}^{2}+\sum_{i=1}^{S} Y_{i}^{2}}
$$

Where $S$ is the total number of amphipod species, $X_{i}$ is the proportion of amphipod $i$ in the diet of species $X$, and $X_{i}$ is the proportion of amphipod $i$ in the diet of species $Y$. Table 57 gives the results of these overlap calculations. Any value greater than or equal to 0.60 is accepted as showing significant similarity. (Zaret and Rand, 1970).

It is clear from the $C \lambda$ values in Table 57 that the proportions of different species of amphipods taken by most fish are dissimilar for the majority of fishes, as in only 18 out of a total of 78 comparisons does $C \lambda$ equal or exceed 0.60 . S. spinachia, T. bubalis, M. scorpius, $P_{\text {. gunnellus and to a }}$ lesser extent $P_{\text {. virens }}$ take similar proportions of the same types of amphipods. Also the proportions of amphipods in the diet of P. minutus and P. platessa are similar. When $C \lambda$ for pairs of related species are examined, it will be seen that the

Table 57. Results of Amphipod similarity calculations comparing the proportions of amphipods taken by different species. The figures in the Table are values for the similarity co-efficient (C $\lambda$ ) as calculated from the formula given in the text.

extent of the use of different amphipods is significantly similar between M. scorpius and T. bubalis $(C \lambda=0.92)$ but the values of the similarity coefficient is much lover in other related species: $C \lambda=0.60$ for cod and saithe, 0.52 for $P$. minutus and P. microps; 0.43 for $S$. spinachia and G. aculeatus and 0.28 for plaice and flounder.

The results in Table 57 indicate that sufficiently different proportions of amphipods are taken by predator species to reduce further the similarity between the fishes diets.

The second most important crustacean food was isopods, occurring in 17 predator species out of 18 and in 7 of them they became a major food group. (Table 56). They were particularly significant in S. spinachia, P. gunnellus, Z. viviparus, and C. melops. Relatively few species were identified, but as in the case of amphipods, there are indications that different species taken by different predators; for example P. qunnellus fed almost exclusively on Jaera sp, whereas M. scorpius mostly took Idotea sp.

Mysids occurred in 14 predator species but only once (in S. spinachia) did they become one of the major food groups.

Shrimps occurred in seven predators and crabs in 10 , reaching significant amounts in the diets of M. scorpius and G. morhua in terms of shrimps and in M. scorpius, T. bubalis and Z. viviparus in terms of crabs. Decapod larvae were important in the diet of the two plankton feeders, Atherina presbyter and $\underline{H}$. lanceolatus but were not utilized by Chaparrudo flavescens. They were also relatively important in partial plankton feeders such as cod and saithe, but not in G. aculeatus.

Calanoid copepods were the major food of all plankton feeders and were also important in the partial plankton feeders cod, saithe and G. aculeatus. Cladocerans were common to 8 fish species; their overall importance was not as high as calanoid copepods and highly seasonal. Harpacticoid copepods were found to occur in all fish species examined. The highest amounts were found in N. lubriciformis where they made up $34 \%$ of the total food; their proportion in other fish varied between $0.1 \%$ in T. bubalis to $12 \%$ in juvenile cod. They mostly occurred in the juvenile members of predators. Ostracods, like harpacticoids were common to most fish, occurring in small amounts. They became a major food group only in N. lubriciformis
C. melops. Except in these two instances, and like harpacticoids, their occurrence was highly correlated with small fish size. Cumaceans occurred in 9 fish species in minor amounts, gaining significance only in A. cataphractus.

Polychaetes were the most important non-crustacean food group common to 15 predator species out of 18. Their proportion in different fishes diets showed much variation, from $1 \%$ in cod to $34 \%$ in plaice. As might be expected they were most important in the diets of the truly benthic species, Plaice, Plounder, P. microps, P. minutus and T.bubalis. In the diet of Atherina presbyter they were present as planktonic larvae. The commonest families, occurring repeatedly in many fishes were Nereidae and Phyllodocidae. As in the case of amphipods, there were indications of some families being more common in some predators than others. As most of the polychaetes could not be identified however, no comparison of similarity of diets with regards to their proportions was possible.

Molluscs, mainly gastropods and bivalves were also commonly taken by 15 species but their occurrences and relative amounts were often small. They became a major food group only in plaice, flounder and C. melops. Once again, some species, such as
plaice, mainly took bivalves, and others like T. bubalis more gastropods, They were present in plankton feeders as planktonic larvae.

Insects, like molluscs and polychaetes were common to 15 predator species out of the 18 examined and were taken in varying proportions. Insect larvae were more common than the adults in the diets. Insects were a major food group in G. aculeatus where they comprised $21 \%$ of diet, but were also relatively important in P. microps. P. gunnellus, and S. spinachia.

This comparison of diets emphasises the conclusion reached earlier, namely that relatively few major food groups are used by predators and that the main differences between diets are caused by different degrees of utilization of the same group rather than feeding on entirely different groups. In this respect, no specialists, i.e., which use one food source exclusively were found among the fishes of Loch Etive. Within any one fish species the major types of food often did not alter throughout the year, although their relative importance sometimes changed. In T. bubalis, for example, polychaetes were more important in the winter months than the summer. Seasonal
variation in the proportions of food taken may reduce the similarity of the diets between species even further.

It is also necessary to consider briefly the food division within a predator species. It has been mentioned earlier that in most species the food of juveniles differed considerably from that of larger individuals. As an example, juvenile Spinachia took many harpacticoids, ostracods and small amphipods, whereas larger specimens fed more on mysids, polychaetes and large amphipods. As the fish size changed, the proportion of different species of amphipods in the diet also changed. The difference in the diet of juveniles and adults were very marked in M. scorpius, G. morhua, $\mathcal{P}_{\text {. virens, }}$ P. platessa and P. flesus. In M. scorpius smaller individuals fed almost entirely on amphipods, and the proportion of ostracods, harpacticoids decreased with increasing body length. In this species, once again, it was found that the type of amphipods eaten varied with fish size. Such differences in the diets of growth stages of a species are of course obscured when the diet of the species as a whole is considered. This clumping produces apparent similarities in the feeding habits of different species, but on closer examination these
similarities are not as obvious and may completely disappear. For example, the diet of young $M_{\text {. scorpius }}$ is fairly similar to that of adult $S$. spinachia whereas the adults of these two species feed on very different types of food. Presumably the larger fish ignore the smaller food items because of the high energy outlay necessary to obtain sufficient quantities, or, in case of benthic animals, they may be harder to pick up from the bottom. On the basis of such observations it is suggested that the age groups of any one species are not or are in only limited competition with each other for food. When the diets of both young and adult fish are relatively similar as in the case of $P$. minutus intraspecific competition would still not be important as larger forms are capable of feeding on a vider variety of food than smaller specimens.

Taking all the above remarks into consideration, it is clear that the food resources available to a fish population are partitioned both inter-and intra specifically and that competition, if it exists at all, is most likely to occur between similar sized individusls of the same species, and possibly, also between different length groups of different species.

As a summary, it can be stated that in Loch Etive, between no two species was a true identity of feeding habits found when the proportions of different food types were considered. The differences between the diet of one species and another were often in the proportions in which the most commonly occurring food types were eaten rather than the exploitation of totally different sources of supply. It is thus thought that no true competition exists between the fish species in Loch Etive.

## GENERAL INTRODUCTION

The results of the ecological work presented in Part I suggested the possibility that the fish were showing a certain amount of selection towards their food.

For example, a few prey species were dominant in the diet of most species. As discussed earlier, this was thought to be mainly due to the greater abundance of the dominant prey species in the environment. The possibility of some selection could, however, not be excluded.

It was also noticed that in a large number of species, that the size of prey taken was related to the size of the fish, larger prey being found in the stomachs of larger fish. Such observations are not uncommon in the study of the feeding habits of fish and several workers have demonstrated that prey size in Pish stomachs correlates well with fish size (Kohler at Fitzgerald 1969; Schultz \& Northcote 1972; Tyler 1972; Moore \& Moore 1973). Such a relationship could be due either to an active selection for prey size or a function of prey catchability or both.

The ecological study further showed that most of the fish species examined were feeding on prey which was capable of movement. The percentage of fast moving prey such as mysids or amphipods was higher in the diet of some fishes than others, other fish species fed mainly on slow moving prey such as polychaetes. The proportion of sedentary prey, bivalves for example, was high only in the diet of a few fish species. It was considered that, in some fishes at least, the selection of moving prey could be either inherent or aequired by learning. This selection, if it existed might also be dependent upon the type and speed of the movement.

All these points suggested the importance of external features of prey such as size and movement which might influence the prey preferences.

The aim of the second part of the present work was to study experimentally the behavioural factors affecting the feeding in order to determine which external stimuli presented by the prey resulted in its selection by the fish.

Detailed descriptions of fish predatory behaviour under laboratory conditions are relatively rare. Tugendhat (1960)
examined the feeding behaviour and the effects of satiation in the three spined stickleback Gasterosteus aculeatus. Brawn (1969) looked at the general feeding behaviour of cod Gadus morrhua. More recently Olla, Samet and Studholme (1972) have given a detailed account of the activity and behaviour of summer Plounder Paralichthys dentatus and Chiszar and Windell (1973) analysed the components of feeding behaviour in bluegill sunfish Lepomis macrochirus.

Studies of the many different aspects of prey selection are also rare. Early studies mainly investigated the ability of fish to respond to different pairs of stimuli. Rowleys (1934) found that goldfish could differentiate between two circles one $10 \%$ larger than the other. Hafen (1935), measuring the responses of phoxinus laevis to different colours, showed that they preferred yellow and green to red, blue and violet. If, however, the same fish was fed on red meat, they later preferred red, demonstrating the effect of learning on colour discrimination. Zunini (1937) investigated size discrimination in the same Pish. Hager (1938) examined contrast preferences and pattern recognition in Phoxinus laevis and Eupomotis gibbosus (L.). Meesters (1940)-made some
observations on size preference in Phoxinus laevis. He also investigated shape recognition by offering the fish triangles and squares in different orientations or presenting the fish with figures on uniform or patterned backgrounds. In addition he found that untrained Gasterosteus aculeatus gave the maximum response to shapes which were closest to their natural food. His experiments on the effects of movement showed that the speed of movement which the fish found most attractive corresponded closely to the speed of movement of their natural prey. Kettner (1948) investigated the colour discrimination in different species and divided them into differeat groups according to their ability to differentiate between colours. He found that different species differed widely in their colour recognition. Herter (1953) examined spontaneous and trained responses of fish to different shapes and shades and found that most fishes could differentiate between different shapes and shades.

In most of the above studies, the workers did not use enough subjects or a sufficiently rigorous experimental design to allow firm conclusions to be drawn. Their results, nevertheless, are interesting in that they show the wide
differences that exist in the responses of different species to visual stimuli.

As it was not possible to investigate factors affecting food selection in all the fishes covered in the ecological studies, three species were chosen to act as representatives. These were Spinachia spinachia; Pholis gunnellus and Myoxocephalus scorpius. Spinachia spinachia is a midwater fish feeding almost exclusively on small crustacea. Pholis gunnellus is a bottom living fish with similar food habits as Spinachia. Mvoxocephalus scorpius is also a bottom living fish with entirely different feeding habits from the first two species. All three species could be found in reasonably large numbers throughout the year and detailed information on their natural diets was already available. It was considerad that a study of the behavioural aspects of feeding under laboratory conditions of these species could contribute to a better understanding of their feeding habits in the field; whether, for example, they showed any form of prey selection or whether they were exclusively opportunistic.

From a behavioural point of view, no studies on Spinachia or Pholis exist in the literature although there is
a large amount of published work on the several aspects of behaviour in Gasterosteus aculeatus, a stickleback related to Spinachia (Tugendhat 1960; Beukema, 1968).

Before any experimental analysis of the effects of various visual stimuli on the feeding of these three species could be conducted, it was necessary to determine and describe their general pattern of feeding behaviour.

The three species were initially kept in tanks and general observations on their behaviour were made. Myoxocephalus scorpius was later abandoned as it vas found to be behaviourally very inactive.

Once a knowledge of their general feeding behaviour had been gained, the response of Pholis and Spinachia to prey size and movement were examined experimentally. For Spinachia
only the effects of shape and shade were further studied.
Finally, the results obtained from both species were compared.

Methods:
A group of locally caught Spinachia spinachia were kept in a large circular tank for some weeks. Eight fishes of total lengtin $80-110 \mathrm{~mm}$ were then placed into separate perspex tanks of 451 capacity and observed individually..

The tanks were covered on three sides and at the bottom with graph paper so that the angles and distances could be measured. A black screen with a slit was placed in front of the tanks. The fishes were observed through these slits and with the belp of airrors arranged above the tanks at an angle of $45^{\circ}$.

The food offered consisted of chopped mussel gonads, squid pieces; freshly killed or thawed frozen mysids, live mysids and live adult Artemia which were grown on algal cultures to a suitable size of $6 \mathbf{- 1 0} \mathrm{~mm}$ in total length.

The sequence of actions during feeding and the various positions of the body in relation to food and to the tank boundaries were recorded on a tape recorder. The tapes were later transcribed for analysis.

## FEEDING BEHAVIOUR OF S. SPINACHIA.

## Methods:

A group of locally caught Spinachia spinachia were kept in a large circular tank for some weeks. Eight fishes of total lengtin $80-110 \mathrm{~mm}$ were then placed into separate perspex tanks of 451 capacity and observed individually..

The tanks vere covered on three sides and at the bottom with graph paper so that the angles and distances could be measured. A black screen with a slit was placed in front of the tanks. The fishes were observed through these slits and with the help of mirrors arranged above the tanks at an angle of $45^{\circ}$.

The food offered consisted of chopped mussel gonads, squid pieces; Preahly killed or thaved frozen mysids, live mysids and live adult Artemia which were grown on algal cultures to a suitable size of $6-10 \mathrm{~mm}$ in total length.

The sequence of actions during feeding and the various positions of the body in relation to food and to the tank boundaries vere recorded on a tape recorder. The tapes vere later transcribed for analysis.

When an individual $S$. spinachia was first placed in the rectangular tank, it kept close to the walls and corners of the tank. Swimning was very fast and the fish appeared to be very agitated. The pectoral fins were fanned rapidly (about 80 times/min), the head was turned from side to side and the fish repeatedly collidea head first with the tank walls and corners, sometimes hitting them with great force. The number of times the walls were hit was quite high in the initial stages up to 48 times/min. Hitting of the walls and corners decreased later as the fish spent more time in the tank.

The fish mostly swam very close to the tank walls describing an eliptical course or a horixontal figure of eight which was repeated a number of times. It repeatedly swam to the bottom of the tank and then upwards in a circular course, almost touching the walls and giving the impression of chasing a moving object. The pattern of swimming and wall-hitting auggested that the lish might be reacting to its ovn reflection. This suggestion is supported by the fact
that most of the swimming was done close to the front wall which was covered with a black screen and was more likely to act as a mirror than the other walls which were lined with white graph paper. As mentioned before, when the fish was first placed into the tank, it appeared very agitated. It seems unlikely hovever that agression would be displayed when the fish was stressed. The hitting of the front wall at these initial stages might therefore be due to the fish trying to escape through the only wall which looked transparent. This swimming close to tank walls persisted however and the repeated swimming up and down close to a wall on a more or less circular course was termed "reflectionchasing". The dorsal fin was erected occasionally during "reflection chasing". This and wall-hitting also auggested a defensive or agressive behaviour.

If conspicuous palatable prey was put into the tank when the fish was engaged in "reflection-chasing" and wallhitting, no interest in the food was shown. Even if a live prey, suspended from a long transparent tube was brought within 1-2 cm of a hungry fish, it was completely ignored. When the fish stopped reacting to the tank bounderies,
swimming becane slower, regular and more random instead of the previous very rapid repetition of a pattern. The fish also began to accept food readily. When this state was reached the acclimatization period was considered to be complete. The time for adaptation to tank conditions was variable, but usually took 3-4 days.
"Reflection-chasing" and wall hitting were occasionally observed with acclimatized fish but such behaviour did not last for long periods. Whenever "reflection-chasing" or wall hitting vere performed, no feeding took place, suggesting that the occurrence of one excluded the other.

BEHAVIGUR APTER ADAPTATION IN THE ABSENCE OF POOD

Once the fish stopped reacting to the tank boundaries it either swam or remsined suspended in midwater. The fish could remain suspended motionless in the water for long periods either horizontally or almost vertically. The pectoral fins were moved slovly, about 48 times/min and the caudal fin undulated gently. The number of eye movements was low and a wide opening of the mouth was occasionally observed.

When swidming, the fish either moved horizontally or
almost vertically. Most of the swimming was done in a relaxed fashion. It swam downards head first with slow movements of the pectorals. The body usually assumed a narrow angle with the bottom of the tank though there were instances where it approached the bottom almost vertically, head downards. It then changed direction and swam upwards again, approaching the surface through an angle or elmost vertically. There was no fixed course which the fish repeated, swimning appeared to be random. It also swam at the same level, usually describing a circle by a full turn. Half turns by which the fish changed direction also took place.

Faster swimming in all planes occurred in short outbursts and was not continuous. Full turns and half turns vere sometimes observed. The pectoral fins vere fanned vith great speed and the caudal fin also moved very fast.
"Yawning" (a wide gaping of the mouth) took place occasionally and was a distinct act. Tawning has been described for a nusber of other fishes. In pinfish Lagedon rhomboides it occurred together with strong erections of the dorsal fins and was found to be correlated with pressure
changes (McCutcheon, 1966) 01la et al. (1972) hold the opinion that yawing is generally associated with the changes in activity. They found that in summer flounder, yawning preceeded some form of activity. Rasa (1971) similarly found that in yellow tail demoiselle, Microspathodon chrvsurus activity increased following yawning. Tugendhat (1960) mentions that yawning occurs in Gasterosteus aculeatus in combination vith erection of the dorsal fins and calls it a confort movement. Morris (1958) in his studies of reproductive behaviour of ten spined stickleback, Pygosteus pungitius, called yawning a comfort movement and commented that yaming was most frequent when the fish was otherwise unoccupied.

In Spinachia yaming was not frequent. It occurred either singly or in succession, about 6-9 times in 30 mins. This is much less Prequently than 01la, Samet. Studholme (1972) found for summer flounder, where up to 33 yawns were recorded in 30 min period. In Spinachia as in pinfish, three spined stickleback and ten spined stickleback yawning was frequently accompanied by the erection of the dorsal fins.

It was not clear from the observations whether yawning
preceeded more intense activity or was in anyway associated with the position of the fish on the bottom of the tank or high in the vater, i.e., in relation to pressure. For example it was not noticed that yawning took place specifically before the fish began to swim after having been suspended motionless or before a change in swimming speed or after a change in depth.

The speed and type of $f$ in movements were naturally related to the movement of the fish, whether it was stationary or svimming; but in addition the speed with which the pectoral fins vere moved was thought to serve as an expression of a particular state. For example, during the Pixation of its reflection in the tank wall by a stationary fish, the pectoral fins would begin to beat very rapidly giving the fish an excited appearance.

The pectoral fins were usually beaten alternately with varying speeds. . In certain states they were moved backwards and forwards in unison.

Erection of the dorsal fin was observed both during swimming and when the fish was motionless. Tugendhat (1960) states thet in the three spined stickleback erection of the
dorsal spines was associated with an abrupt stopping of morement. As mentioned above, McCutcheon (1966) commented on the association of yawns with pressure changes. In

Szimachia erection of the dorssl fin frequently accompanied a garn or occurred when the fish stopped swimming. Fin erection also occurred independently of yawns, however, dnring reflection-chasing, after swallowing too large a food or during swimming. Fin erection was probably involved in saintaining stability. Dorsal fin erection in Spinachia is ihus performed for a variety of reasons.

In general it was possible to recognise three states ty?ified by the various combinations of the actions des-ribed above. The states are sumarised in Table. 58 .

Seerching behaviour
When searching for food, the fish would swim horizontally vish pectoral fins beating slowly and regularly. It would epproach the bottom of the tank from the horizontal by tilting the head downards and forming a narrow angle with the bottom. The angle of approach varied betveen $10-90^{\circ}$ but usually was $45-65^{\circ}$. The eyes would move to examine the bottom, the head

| Action | Swimming | Pectoral | Yawns | Dorsal Fin |
| :--- | :--- | :--- | :--- | :--- |
| State |  | Movement | Erection |  |
| Relaxed | Slow, continuous | Moved alternately | Occasional Occasional- |  |
|  | regular or absent | $0.5-1$ times/sec |  | rare |
| Excited | Fast, | Moved alternately | Rare | Rare |
| discontinuous | $2.1-2.8$ times/sec |  |  |  |
| Stressed | Slow, jerky | Moved alternately | Occasional Occasional |  |
|  |  | or synchronously |  |  |

would also be turned slightly. The fish then swam upvards, the area being examined all the time by eye movements and slight head turns. Changing of direction by full turns and half turns. of the body also took place.

The fish was not able to see prey above or below it, neither
did it respond to prey clese to, but behind it, suggesting that the field of vision is fairly restricted and that vision plays the dominant role in food selection. Once the prey had been seen, the fish was able to capture it from the surface, the bottom or suspended in midwater.

## Description of prey capture and feeding sequence

The feeding sequence began when the prey animal was sighted by the fish. If the fish was interested it orientated towards the prey ( 0 ), that is, it changed its body direction towards prey. The prey was then visually fixated (Pi) by converging both eyes upon it.

Pixation was followed by an approach towards the prey in a straight line (AP). Alternatively the fish could stop (ST); move on (MO) past the prey with a slight change of direction, or turn away from the prey (TA) with a full turn of the body. ST could occur before the fish approached the prey or before it turned away and moved on. An approach was either followed immediately by an attack (AT); defined as a sudden dart towards the prey, or by a $S T$ for a fev seconds. If the fish stopped, the rate of movement of pectoral and caudal fins
would increase to a maximum and the body vould assume a typical $S$ shape, called the $S$ bend (SB) beture attacking. Occasionally after stopping and showing an SB the fish would back (B), that is, swim backwards a short distance still facing the prey. If the fish backed, it could either reapproach the prey, move on or turn away.

If the attack was successful, the prey was grasped (GR) in the jaws by the head or sideways. If unsuccessful, a miss was recorded ( $M$ ). If the prey was missed, the fish might either reorient, fixate approach and repeat the attack or it could move on in the sane direction.

Once the prey was grasped, whether it was immediately ingested or not depended on the prey size. If the prey was of a suitable size it would be ingested (I), that is, be completely taken into the mouth either head firat or if grasped sideways, from the middle of body by folding it into half.

If the prey was too large, it would be held between the jaws, (hold, H) while the fish swam round. The fish pressed its jaws tightly while holding the prey thereby killing it. The prey might then be spat out (SP) and the AT $\rightarrow$ GR $\rightarrow I$
sequence repeated. Alternatively, the fish might move on or turn away.

With palatable prey of a suitable size, ingestion resulted in swallowing (SW) and although there was no recognisable act which marked swallowing, a prey was considered to be swallowed when the fish began hunting again or engaged in other activities.

If the prey was large, chewing movements (CH) were observed before swalloving. Chewing usually implies crushing prey between the teeth, but in this case the movement suggested that the fish was breaking the prey by grating it against the gill rakers. The teeth of Spinachia are small and are grasping raiher than biting teeth. (See Fig. 33 ).

The prey might then be swallowed or spat out whole or in 2-3 pieces. The fish then either regrasped the prey after repeating the $0 \rightarrow P \rightarrow A P \longrightarrow A T$ cycle and $H$ was finally swallowed or abandoned.

After swalloving, regurgitation of prey (R) sometimes took place. $R$ was differentiated from SP by the time interval passing after I. SP was usually instantaneous or preceeded the chewing movements. $R$, if it occurred, took
place after the fish had swam for sometime or even captured another prey. After regurgitation the fish usually left the prey and goved on, turned away or in some instances it was regrasped, ingested and swallowed.

111 the observed feeding acts and their relationships with one another are given in Fig 16. The left hand colum in the figure with seven steps from 0 to $S W$ shows the bssic feeding sequence. Providing the fish was hungry, prey size and taste were suitable and the fish did not miss
 could be completed without a break vithin a few seconds.

Devie:ions from the basic feeding sequence; sequence complexity
and $1 \in \mathrm{ng}$. h .
jeveral factors appeared to effect the feeding sequence complexity. They vere
a) bunger level of the fish
b) prey size
c) prey palatability
d) prey movement
a) iith gradually increasing satiation, the basic chain might

Column 3 shows the actions that result in the
fish being further away from the prey.

Column 1
Column 2
Column 3
break at any point before the swallow stage, and sume of the steps shown in Pig 16 would be repeated, thereby increasing the total number of acts performed in the feeding sequence. As satiation increased, the chain was usually broken at progressively earlier stages, that is at AT, AP, FI, 0 stages. There was also an increased number of stops, turn aways and move ons. Pinally, with complete satiation the feeding sequence would go no further than the first step, orientation.

In other words, with maximum hunger and with palatable saall prey, and if not missed during aT, the minimum number of stages was confined to seven. With increasing satiation, the sequence complexity and length first increased, the total nurber of steps involved being higher than seven. Then, with maximum satiation they were reduced to a few initial stages.

These observations suggested that the fish became more selective but not less responsive with decreasing hunger. b) With large prey the basic feeding chain was mostly affected at the grasp stage with an increase in the number of holds, spits and grasps. Chewing movements were commonly observed after ingesting a large prey. The fish might also
exhibit the stress condition at this stage by swiming very slowly, occasionally erecting the dorsal fins or laying on the bottom. The prey might be regurgitated after sometime and either swallowed again or abandoned.
c) The effect of less tasteful food of suirable size on the feeding chain was similar to that of large prey. A stale piece of food might be spat out, grasped and ingested a number of times. Chewing movements were sometimes observed as if the fish was having difficulty in swallowing the food, which might eventually be either swallowed or rejected. Regurgitation seemed to occur more frequently with less tasteful or very large food than with palatable small food.
d) Movement of prey affected the feeding acts before and after the attack stage. The increased morement of the pectoral fins accompanied by the S-bending of the body were consistently observed before the fish attacked a live prey, but were less frequently seen with dead prey.

The $S$-bend seemed to be an action performed before the fish made a sudden attack at an object which it anticipated capable of movement. The fact that S-bends were sometimes observed before the fish started hitting its oun reflection
on the tank walls supported this view. Also after the fish had been feeding on live animals, a dead mysid or Artemia lying on the bottom of the tank initially evoked an $S$ bend but after one or two attempts the fish stopped showing S bends to dead animals, indicating some degree of learning. Movement of the prey also increased the number of misses, causing a restart of the feeding sequence, hence increasing the sequence complexity. The attacks made to non moving prey were more successful than those made to moving prey.

PREY SIZE SELECTION IN S. SPINACHTA

Introduction
As discussed earlier in the ecological survey it was noticed that the size of prey in S. spinachia stomachs varied with the fish size. As the fish size increased, the size of the prey in the diet bocame progressively larger. The same phenomenon was repeatedly observed in the other fish species studied and was more marked in some species than others.

The behavioural nature of prey size selection, although frequently observed in the studies of fish feeding, is not
vell documented although there are a few laboratory
observations which suggest the degree of predation is influenced by prey size. (Zunini 1937; 01la, Katz and Studholme 1970; Vare 1972).

The aim of this part of the work was to determine experimentally whether size selection is an innate behaviour pattern of the species, whether it is solely or partially a function of prey availability or whether selection is determined by the mouth size of the fish.

Choice of prev for the experiments.
Before the size dependent selection of food by Spinachia could be studied, it was necessary to decide on the food to be used in the experiments.

A group of freshly caught Spinachia were kept in a large circular tank for 6 to 8 weeks, fed on a mixed diet of chopped mussel, squid pieces, thawed frozen mysids and live mysids,

## Neomysis integer.

Swimming mysids were found to be taken markedly in preference to mussel, squid pieces and also thaved frozen mysids. As mentioned previously, Spinachia feeds primarily
on amphipods, and mysids are not the most important food item of their diet in the field. Mysids were, however, found to be very readily taken by captive $f$ ish and compared to amphipods they could be collected in large numbers from the mouth of a nearby stream. They were also easy to keep alive in the laboratory. Mysids were therefore chosen as the prey organisms for the experimental work.

The relationship between mysid size and fish size in the field.
In the field fish were collected from Loch Etive, using a beach seine net or a push net in a depth of less than 8 m . The sampling period was October 1971 to October 1972. After capture, the fish were immediately preserved in $70 \%$ alcohol. They vere later dissected under a binocular microscope, the stomach contents were identified and the total length of any mysids present recorded.

The results of the mysid size anslysis for the fishes caught in the field are given in Fig 17. The frequency of occurrence of mysids is relatively low and when they are present it is usually in low numbers. In addition, mysids are softbodied animals and are frequently broken in fish stomachs;

Fig. 17. The relationship between the length of S. spinachia (cm) and mean length of mysids (mm) found in the stomachs of fish caught in the sea.

this further reduces the number of mysids available for any size analysis since only intact prey whose size could be reliably measured vere included.

Regardless of these factors, however, Fig. 17 shows that a significant correlation exists between the mysid size and Pish size in the field $(r=0.60 ; n=83 ; \rho<0.001)$. Each point on the graph represents the mean prey size for an individuel fish.

Out of 83 fishes analysed, the majority were between 85 man to 105 an in length and a wide mean prey size is apparent from the considerable scatter in this region. The fishes above 110 m in length with measurable mysids in their stomachs vere relatively few, but these mysids vere of a distinctly larger size.

Thus, in S. spinachia the relationship between the fish and prey size in the field was found to be very marked. Similar results have been obtained for many other fish vith different habits and different prey (see, e.g., Kohler \& Fitzgerald, 1969; Schutz \& Northcote, 1972; Tyler, 1972; Moore \& Moore, 1973).

Two experiments were conducted with free swimming mysids. The purpose of the first experiment was to determine whether size selection similar to that found in the field could be observed in the laboratory under simulated field conditions. By field conditions it is meant that a dense Neomysis integer population with a natural size distribution should be present in the tank with differences in swimming speed and tail flip i.e., with differences in their capacity to escape predation. Since Neomysis integer swarm and shoal in shallow water in nature, this is not such an artificial situation as it might appear.

In Experiment 1 the response of a group of different sized fishes to different sized prey was observed in order to see whether size selection could be reproduced in the laboratory with $f_{1}$ e swimming mysids. A dense population of mixed sized Neomysis integer were kept in a tank $90 \times 45 \times 45 \mathrm{~cm}$. The size distribution of mysids in the tank was assumed to reflect that in the field at this time of the year (July), but the size-frequency distribution was not determined. According to

Mauchline (1971) Yeomysis integer has a size distribution within the range of $5-18 \mathrm{~mm}$, with a mean of 12 mm in July. Thi-ieen fish, brought directly from the field were deprived ef Eood for 48 h and then put into the tank. After 2 h the fish vere killed and stomach contents were analysed.

Line 2 in Fig. 18 shows the relationship between the fish size and prey size under such conditions. The number of predators was relatively few but they had a wide size range, between 50 to 123 mm . A very strong correlation was found between Soinachia size and the prey size ( $\mathbf{r}=0.98 ; \mathbf{n}=13$, $\rho<0.001$ )

In the above experiment the frequency of different size groups in the mysid population was not measured, so that, if very few large and small mysids were present in the tank the mean prey size taken by the large and small fish could approach one another so reducing the difference in chosen mean prey size. Experiment 2 was carried out to see whether size selection beceme more evident when the numbers of smaller and larger misids vere increased in the tank.

Experizent 2 was otherwise similar to Experiment 1, but this time the relative abundance of different mysid size

Pig. 18. The relationship between length of S. spinachia and mean prey size (mm) in the laboratory. Line a) Expt. 1 with an uncontrolled mysid population. Line b) Expt. 2 with a controlled mysid population (see text).
groups was strictly controlled in order to diminish any modification of size selection which could be caused by differences in the numerical availability of mysid size groups. Mysids of all sizes were not present in equal numbers in Experiment 1. This difference in abundance of the size groups could affect the number of large and small mysids caught by the fish, thereby affecting the mean prey size taken. For example, if there were only a few small mysids in the tank, a small fish might be more likely to take larger prey and thereby increase its mean prey size. Similarly, the virtual absence of large mysids could reduce the mean prey size of a large fish. This could cause the relationship between the prey size and fish size to appear less marked. In order to reduce this possibility, equal numbers of all prey sizes were presented. Unfortunately it vas not possible to measure accurately live mysids below 9 m total length without damaging them, so that a prey size range of 9 to 23 mm had to be selected. The mean length of the controlled mysid population (Experiment 2) was, therefore much higher than the uncontrolled population (Experiment 1). Twenty mysids in each mm length group were measured,
put into the tank, and allowed to settle. Twenty seven Preshly caught fish were deprived of food for 30 h and then transferred to the mysid tank, allowed to feed for 3 h , killed and the mysids in their stomachs were measured. Line b in Fig. 18 shows the relationship between fish size and prey size when equal numbers of prey in each mm size group were present. Again, as in Fig 18 line a, each point on the figure represents the result for an individual fish.

It is apparent from line b (Fig 18) that when the numbers and the sizes of the mysids were controlled, the positive correlation between the fish size and prey size still holds ( $\mathrm{r}=0.78 ; \mathrm{n}=27 ; \mathrm{P}=<0.001$ ). Purthermore, the slopes of the two lines are not significantly different ( $\boldsymbol{\rho}>0.10$ ) suggesting the relationship between the prey size and fish size is in both cases similar, i.e., a given change in fish size is accompanied by a constant change in prey size, implying that, for example, a fish 1 cm larger than another will on average hare a mean prey size $\approx 1.5 \mathrm{~mm}$ larger, whatevar the range of prey size available. The fact that the relationship is similar shows that . line a is not an incidental result of unequal numerical availability of smaller and larger mysids. A comparison of lines
$a$ and $b$ also indicates that size selection did not become sharper with increased number of lerger mysids.

The intercepts of two lines ere statistically different ( $P<0.001$ ) because the smallest $E$ ㄴid size group present was 9 man in Experiment 2,much higher than those in Experiment 1. The difference indicates that the fish can alter their average prey size according to the range of prey available, so long as the available range is within the limits of their own range of selection. Por example, the mean prey size for a 60 mm fish in Experimeni $f$ was 7 mm whereas in Experiment 2 when mysids below 9 were not available, it was 10.2 mm .

Sone of the fish stomachs hać eny mysids above 18 mm although equal numbers of larger wisids up to 23 mere also present in Experiment 2.

Observations in the laboratory of the relationship between S. spinachia and mysid size when both were free swimming show a close similarity to the field results. When the only prey available was larger than they would normally take in the field, the fish take the nearest size they can find within their preferred range, but do not consume much larger prey even if its abundance is high (Experiment 2).

## The relationship betieen mysid size and fish size in the

laboratory using stationary mysids.
In the experiments described above, escape movements of proy vere not restrizted. Also, a group of mixed sized fishes were used which were likely to differ in their swimning speed and perhaps in visuel acuity. All these factors would affect the prey discovery and capture efficiency of fishes. Experiments 1 and 2 did not therefore distinguish between the possibilities that,
a) different fish of different lengths respond differently to different sized prey; or
b) fish responded to all prey but only larger fish could catch large prey due to the differences in fishes swimang speed, mouth size and possibly, risual acuity.

If assumption (a) is true, then selection should be demonstrated when all prey are equally catchable, but if assumption (b) be true, then no selection would be found in the above conditions. To determine which of these assumptions was correct, it was necessary to perform an experiment (Experiment 3)* in which all prey re:e equally available hence maximising the capture efficiency of different size predators.

In Experiment 3 fish were placed into Perspex tanks of $47 \times 31 \times 31 \mathrm{~cm}$, arranged on a bench. The tanks were divided into a small resting compartment and a larger feeding compartment separated by a sliding door. The tanks were covered on three sides so that once the fish was in the feeding compartment, it could not see outside the tank. In order to minimize disturbance by the observer, mirrors were arranged at $45^{\circ}$ above the tanks and the front walls of the tanks covered with a black screen. The fish were observed through a slit in the screen and with the aid of mirrors. The tanks vere so arranged that their illumination did not differ significantly. The temperature of vater varied between $10-12^{\circ} \mathrm{C}$. Prior to experiments the fishes were kept singly in these tanks for a minimum of 8 veeks and fed on mysids during this time.

In Experiment 3 only the responses of fish to prey of different sizes was under investigation and it was, therefore, necessary to eliminate the differences in the availability of different sized prey. The object of the experiment was to present to each fish a set of food which could be seen equally and also equally easily taken in order to equalize the chances
of discovery and capture for all the prey presented.
The mysids were presented to the fish attached to the ends of fine transparent tubes, 1 mm in diameter. The position of the tubes were adjustable so that the mysids could be presented all at the same level and with equal distances between them. The food was suspended from the ends of the tubes in a loop of very fine nylon fishing line. Preliminary observations showed that four tubes at 5 cm intervals, arranged in a straight line 10 cm above the bottom of the tank and facing the resting compartment at a distance of 25 cm was the best arrangements, where all the prey could be equally seen. Preliminary observations also showed that immobilized living mysids were taken in preference to the same sized dead mysids. Living mysids were therefore used to keep the feeding responses at the optimum level.

Neomysis integer were caught and kept alive in a separate tank. For each presentation they were caught, their total length measured, and they were then looped to the ends of the tubes. At each presentation, four mysids of two different sizes were arranged as a set. The difference in size between the two pairs of mysids was kept as near 5 mas
possible. They were arranged in different orders at each presentation to eliminate the effect of conditioning to a particular arrangement. When two of the same size or a single mysid remained in the set, a new set was presented. The presentations continued until the fish stopped feeding.

Ten fishes between 72 mm and 124 mm , observed singly, were used for this part of the study. The deprivation time was 24 h and was kept constant throughout the experiments. Experiments were always conducted at the same time of the day. The sequence in which prey were taken and the time taken to respond to each prey was recorded. The response to prey was recorded as either positive or negative. Positive responses were the complete feeding responses beginning with an approach to the prey and resulted in swallowing, or in some cases ending in persistent strong attack. Negative responses were ones in which the fish did not attack or swallow the prey. The first time the fish was presented with a set of four mysids after 24 h deprivation is called the first presentation. The first presentation has certain characteristics, namely, the time for the fish to respond to all four prey vas shorter than the subsequent presentations and
unless some mysids were too large to be taken, they were usually taken in a row indicating indiscriminate feeding. By indiscriminate feeding is meant that the fish moved down the line of tubes taking one mysid after another. The percentage of negative responses in the first presentation was also very small.

The effect of satiation on the fish-nysid size relationship. Fig 19 shows the changes observed in the fish mysid size relationship for 10 fishes in successive presentations. After the third presentation the fish were not hungry and the number of positive responses was lov. Because of this and their similarity, the third and subsequent presentations are combined as "third plus" prsentations.

In Fig 19 the mean prey size taken $\mp 1$ standard deviation in each presentation is shown for 10 fish. As it will be seen from the legend to Fig iy the total number of prey taken was extremely large in all presentations hence the values of the correlation coefficient, $r$ for the relationship between fish and mysid size could not be tested using standard statistical tables. The significance of $r$ was

Fig. 19. The relationship between the length of Spinachia and mean prey size in the laboratory in successive presentations.
a) First presentation, b) Second presentation
c) Third plus presentations. The points plotted are the means $+{ }^{-}$1SD.

therefore tested using $\in r$, the standard error of $r$. $r$ is significantly differenz from zero if its value is thre or more times its own standard error (Simpson and Roe, 1939). The standard error of $r$ was calculated by $\sigma r=\frac{1-r^{2}}{N} \quad$ where $N=$ number of observations. $r$ values for first, second and third plus presentations are given below in Table 59.

Table 52.
$r, \sigma_{r}$ and the ratio of ${ }^{r /} \sigma_{r}$ values in successive presentations.

Presentation Number

| I | II | III + |
| :---: | :---: | :---: |
| $r$ | 0.147 | 0.272 |
| $\sigma_{r}$ | 0.003 | 0.031 |
| $r_{r} 4.9$ | 8.8 | 0.353 |

The figures show that the correlations between the fish size and prey size taken vere significant in all presentations. The $r$ values increased progressively from first to third plus presentations indicating that the relationship between fish size and prey size became more and more asrked as satiation increased. This point
was further tested by comparing the regression coefficients of each line in order to see whether the observed increase in prey size with fish size in each presentation were sigaificantly different from one another. The regression coefficients were compared by using the formula:

$$
t=\frac{b_{1}-b_{2}}{\text { standard error of the difference between } b_{1} \& \dot{o}_{2}}
$$

Where $b_{1}$ and $b_{2}$ are the regression coefficients of the lines being compared (Quenouille, 1950).

The results of this comparison are given below.

Table $60^{\circ-}$ Comparison of the regression coefficients of the successive presentations (I) = first presentation, $(I I)=$ second presentation, (III+) $=$ third, plus presentations; $D F=$ degrees of freedom. $P=$ probability.

|  | Comparison of presentations |  |  |
| :---: | :---: | :---: | :---: |
|  | (I) \& (II) | (I) \& (IIIt) | (II) \& (III+) |
| t | 2.6714 | 4.576 | 2.205 |
| D.F. | 1946 | 1744 | 1548 |
| P | $<0.01$ | $<0.001$ | $<0.05$ |

The $t$ values showed that the fish - mysid size relaticnsinip was significantly aifferent between successive presentations. The greatest difference was found between first and third plus presentations and the least difference beteeen second and third plus presentations.

The results suggested that increasing satiation produces a more selective response to prey size. Ásimilar relationship betreen the degree of hunger and selectivity has been demonstrated for other fishes. (Ivlev 1961; Chiszar and Windell $1973^{\circ}$.

Pig 19. also shows the staniard deviations for the mean pres size taken by each fish in each presentation. The stasciard deviations decreased froد the first to "third plus" presentation for each fish except for the 106 and 110 mm fishes. The decrease was, howerer, not very marked except for the smaller fishes. This suggested that the spread about the mean was quite wide in all presentations, showing that the prey size ranges taken in different presentations overlapped considerably. for individual fishes.

The numerical availability of different size groups were not equal in different presentations and the number of prey taken reflected in some cases only the availability of a particular size group and could not be attributed to selection. In order to follow the changes which occurred with different presentations it was necessary to consider the proportion of prey taken out of the total number of prey offered in each size group.

Fig 20 shows the different degrees of size selection operating at each presentation for three individual fishes with total lengths of $72,402,124 \mathrm{~mm}$. The figure demonstrates the different patterns observed in three of the 10 fishes examined. The results for the remaining seven fish are given in Table 6\%.

In Fig 20 the prey taken in each size groun is expressed as the percentage of the total number of prey presented in that size group.

The first point that is apparent from Pig 20 is that the proportion of prey taken out of the total number of prey offered is different in different size groups and a pattern is apparent in each fish which indicates selective feeding.

Pig. 20. The change in the pattern of size selection with increasing satiation for three Spinachia of
a) 72 mm , b) 102 mm and c) 124 mm .

- First presentation; 4 second presentation; © third
plus presentations.

For the 72 mish in the first presentation the percentage of prey taken renained high from 5.5 mm to 15.5 mm prey size, then decreased reaching zero at 23.5 mm . In the second and third plus presentations the percentage prey taken remained still very high at the lower end of the size range but decreased steadily at the larger prey size groups. The decrease began after 13.5 mm in the second presentation but still remained above $50 \%$ up to 17.5 mm size group decreasing sharply afterwards.

In the third plus presentations the percentage of prey taken began to decrease earlier, at 11.5 marey size, reached the $50 \%$ level at 15.5 mm size group, thereafter decreasing steadily until it reached zero at 19.5 mm prey size.

For the 102 mm fish the prey size ranges offered were the same as 72 mm fish; $5.5 \mathrm{~mm}-23.5 \mathrm{~mm}$. In the first presentation the percentage of prey taken remained high throughout the offered size range and no pattern was apparent. In the second presentation the percentage of prey taken decreased slightly in the lower and upper ends of the size range, but the greatest percentage of prey offered were still
taken between 7.5 mm to 21.5 mm , indicating very little size discrimination within this range. The clearest pattern was observed in the third plus presentations where the percentage of proy taken increased steadily from 5.5 mm to 13.5 mm and decreased from 13.5 mm onwards.

For the 124 nua fish prey size range available was 7.5 mm to 23.5 mm .

In the first presentation, as in the other fishes, the percentage of prey taken did not vary significantly with prey size and remained at a high level for all size groups offered. In the second and subsequent presentations a pattern opposite to that shown by the 72 mm fish was observed, that is, the percentage prey taken decreased with decreasing prey size and as before the greatest decrease occurred in the third and following presentations. The percentage of prey taken remained below $40 \%$ at the smaller end of the size range up to 13.5 mm , then increased gradually remaining at a high level between 15.5 mm to 22.5 mm .

If Table 61 is examined, it will be seen that for most fish in the first presentation the percentage of prey taken out of the total numbar of prey offered remains high throughout
Table 61. Varintion in the proportion of prey taken in different size groups in successive presentations.

> Table 61, cont.
> $\begin{aligned} & \text { Fish } \mid \text { Presentation } \\ & \text { size } \\ & \text { number }\end{aligned}$
the size range offered for most fishes. As the fishes become more satiated, a preferred size range within which the highest proportion of offered prey is taken begins to be apparent.

Fig 20 and Table 61 show that the overall size range of prey that could be taken is quite wide.

During the observations it was noticed that when four prey of different sizes, two large and two small were offered as a sat, the fishes generally took the prey in a row in the first presentation. The Pish appeared to be much more discriminating in its choice of prey in the second and subsequent presentations. It was therefore considered that the order of choice could offer a good measure of selection.

If size selection were operating and there are four mysids in two different size groups to choose from, all equelly available, then the first and the second choices would be the most important indicators of selection. On the other hand, if prey were taken indiscriminately, then one would not expect the ratio of first and second choices to third and fourth to differ greatly from unity.

In Fig. 21 the percentage of prey taken as fisst and second

Fig. 21. The percentage of prey taken as first and second choices in the first and second plus presentations for 3 Spinachia of

negative responses. Circles indicate first presentations
and triangles represent second plus presentations.

choices by the same three fishes as in Fig 20 are plotted against prey size in order to demonstrate the order of choice in successive presentations. Table 62 gives the results for the other fishes used in the experiments. Figs 19 and 20 both demonstrated that the relationship between fish and mysid size become more marked with increasing satiation, but the differences between the results of the second, third and subsequent presentations were the least different (see also Table 60. ). To increase the number of observations in each size group, the second and subsequent presentations have been combined in Fig 21 :

Por the 72 mm fish the percentage of prey taken as first and second choices shows the same pattern both in the first presentation and in the second plus presentations, namely, the proportion of first and second choices remain above the $50 \%$ level between 5.5 mm to 12.5 mm with a peak at 9.5 mm , then decrease towards the larger end of the size range. The percentage of first and second choices are higher within 5.512.5 mm size range in the second plus presentations indicating a greater degree of selection.

The lower curves give the percentage of negative responses
in the first and second presentations. Negative responses in both cases increased in the region where the proportion of prey taken as first and second choices dropped. Once again, the increase in the percentage of negative responses is greater at the higher end of the size range in the second plus presentations when compared to the first presentation.

Por the 102 ara fish the percentage at first and second choices vere below $50 \%$ up to 11.5 mm and above $50 \%$ from 11.5 mm to 21.5 mm , no obvious pattern being apparent in the first presentation. In the second plus presentations the percentage of first and second choices presented a clear pattern. They were under $40 \%$ in the 5.5 mm to 7.5 mm prey size group, from 7.5 mm onwards they increased and were above $50 \%$ level between 9.5 mm to 15.5 mm , decreasing to $40 \%$ level between 17.5 mm to 23.5 mm . The percentage of negative responses were high at the smaller and larger ends of the size range in both first and second plus presentations.

Por the 124 mish the percentage of first and second choices in the first presentation fluctuated around $50 \%$ throughout the size range. The values were slightly under $50 \%$ level between 7.5 mm to 13.5 mm and slightly above it

between $13.5 \mathrm{~mm}-23.5 \mathrm{~mm}$. In the second plus presentations the percentage of first and second choices was around $43 \%$ in the region of 9 to 11.5 mm prey size, then increased from 11.5 mm
 range. Also the percentage of negative responses were highest in the lover end of the size -ange. The pattern of negative responses were similar in both first and second plus presentations but the pattern was more accentuated in the second plus presentations.

Table 62 shovs that for some of the fishes a size range where most of the prey were taken as first and second choices vas already apparent in the first presentations but became more clearly expressed in the second plus presentations. For the remaining fishes the percentage of prey taken as first and second choices fluctuated around $50 \%$ level with no apparent pattern in the first presentations; a range where this percentage was highest being only apparent in the successive presentations.

Pig 21 -nd Table 62 once again suggested that the fishes had a preferred prey size range, which became more epparent in successive presentations.

The preferred size range as estimated from the results of the experiments given in Pig 20. Table 61. and Fig 21 and Table $62^{\text {a }}$ agreod closely, although the maxima were not alvays found in the same size group.

Estimation of the zaxinun swallowing canacity of the mouth.
Figs 20,21 and Tables 61, 62* indicated that there was a preferred size range within the range of prey sizes offered to the fish. It was however not known whether this preferred range rê̂jected to some extent the capacity of the mouth of the fish, prey only being taken within the size range that the fish could swallow, with negative responses being shown to prey which ws too large. It was of interest therefore to compare the maximus size of the prey that could be taken by the fish with the size group for which they showed the highest preference.

The size range offered to the fishes had to be chosen according to the erailability of size groups of mysids in the field and, as mentioned earlier, it was difficult to find very larg. mysids. Por this reason the maximum prey size which fishes were capable of taking could not be estimated from the
laboratory observations, because the results, especially in the case of larger fish might well only reflect the upper limit of the size range offerred to that fish.

Field results and laboratory observations showed that Spinachia took mysids whole and usually did not break them into pieces. If the maximum mouth gape of the fish was known, it would then be possible to calculate the maximum size of prey they could swallow whole.

60 Pishes with total length varying from 74 to 118 mm were caught and killed by immersing in $70 \%$ alcohol for a few minutes. They were then immediately removed from the alcohol to prevent the jaws stiffening. The mouth capacity was measured by inserting fine drills of gradually increasing diameter into the mouth. When a drill could not be eased any further into the mouth, its thickness was considered to be equal to the maximum mouth capacity.

Pig 22. shows the relationship found between the fish size and maximum mouth capacity. The correlation was found to be significant at the $0.1 \%$ level ( $n=60, r=0.874$ ).

From the regression line in Fig 22 it was possible to predict the maximum thickness of any prey the fishes were

Fig. 22. S. spinachia. The relationship betveen the fish length and maximum mouth gape.

Pig. 23. The relationship between the length and maximura body thickness of mysids.

5 mm to 22 mm . Occe again the correlation was found to be very significant $(n=110, r=0.957, p=0.001)$.

Knowing the zaxizun gape of the mouth of the fish of different lengtrs (Fig 22 . Table 63). it was possible to estimate from the regression line in Fig 23 the maximum length of mysids $2=$ one fish could theoretically srallow. For the same 10 fishes the maximum length of mysids they could possibly take are given below in Table 64

Table 04 Esti-etes of a 4 imum mysid length that fish of
different lengths could swallow.

| Fish length $(\mathrm{mm})$ | 72 | 75 | 93 | 98 | 99 | 102 | 106 | 110 | 116 | 124 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Max length of | $18.1$ | 19.0 | 22.6 | 24 | 24.4 | 25.3 | 26.4 | 27.6 | 29.5 | 31.8 |
| mysid that |  |  |  |  |  |  |  |  |  |  |
| could be | - |  |  |  |  |  |  |  |  |  |
| swallowed (mm) |  |  |  |  |  |  |  |  |  |  |
| Ratio of |  |  |  |  |  |  |  |  |  |  |
| fish length | 3.98 | 3.95 | 4.1 | 4.08 | 4.06 | 4.03 | 4.01 | 3.99 | 3.93 | 3.91 |
| max mysid length |  |  |  |  |  |  |  |  |  |  |

The figures in Table 64 . show that tine zaximum size of mysids the fishes were capable of swallowing vas approximately $\frac{1}{4}$ of their total length, and the ratio $\frac{\text { fish length }}{\text { max. } \operatorname{mosid} \text { length }}$ is independent of fish length.

It will be seen from these figures that the size range offerred to the fishes used in size selection experiments covered the maximum size of the whole mysid that could be swallowed for $72,75,93,98 \mathrm{~mm}$ fishes but the offered ranges did not include the upper limit of mysid size thich could be swallowed for the remainder.

In Fig 24 the maximum and optimum jzey size groups are plotted against the fish size. Line a in Fig 24 shows the maximum possible size of mysid that fish could take whole. Apart from the mysid sizes corresponding to the fish sizes used ! in the experiments, calculated maximum mysii sizes for the fishes of $80,85,90,100,120 \mathrm{~mm}$ total length are also included to obtain a more accurate regression line. (For line a, $\mathrm{n}=15, \mathrm{r}=0.994, \mathrm{P}=<0.001$.

In the second and subsequent presentaidezs the prey size where the percentage of prey taken as firs: asd second choices was maximum was taken as the optimal prey size for that

Fig. 24. S. spinachia. The relationship betveen maximum prey size (Line a), optimal prey size (Line b) and fish length.

particular fish. (See Fig. 21 Table 52, Line b in Fig 24 shows the relationship between the optimal prey size and fish length for 10 fishes. It clearly demonstrates the fact that the optimal prey size (size group for which the preference shown was highest) is much below the values of the maximum prey size that could be taken in all fish sizes examined. Optimal prey size was estimated from Fig 21 and Table 62 as the mysid length which was taken the greatest number of times as first and second choices in the "second plus" presentations. The estimates of the optimum prey size and the relationship between fish length and optimum prey length are given below in Table 65.

Table 65. The ratio of fish size to optimal prey size for 10 Pishes.

| Pish size (mm) | 72 | 75 | 93 | 98 | 99 | 102 | 106 | 110 | 116 | 124 |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Optimal prey |  |  |  |  |  |  |  |  |  |  |
| size (mm) | 9.5 | 7.5 | 11.5 | 11.5 | 13.5 | 13.5 | 13.5 | 15.5 | 17.5 | 17.5 |
| Ratio <br> Pish length <br> Optimal prey <br> length | 7.7 | 10.0 | 8.1 | 7.3 | 7.6 | 7.6 | 7.9 | 7.1 | 6.6 | 7.1 |

Average ratio $=7.8$

The ratio of fish size to optimal prey size (Table 65) fluctuated around the mean value of 7.8 and was not found to fish length be as constant as the max. prey length ratio. These figures suggest that the optimum size of mysid which fishes select is around $\frac{1}{6}$ of the fishes total length.

If the thickness of optimal prey is estimated from the regression line in Fig 23 for the 10 fishes used in the experiments and related to the mouth capacity, the following $\frac{\text { prey size }}{\text { mouth size }}$ ratios are obtained (Table 66).

Table 66. Ratios of optimal prey size for fish of different mouth size
lengths.

| Fish size (mm) | 72 | 75 | 93 | 98 | 99 | 102 | 106 | 110 | 116 | 124 |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Mouth size (mm | 2.41 | 2.52 | 2.95 | 3.13 | 3.17 | 3.28 | 3.42 | 3.56 | 3.78 | 4.06 |
| Optimal prey <br> size (mm) <br> (thickness) | 1.38 | 1.14 | 1.62 | 1.62 | 1.86 | 1.86 | 1.86 | 2.10 | 2.35 | 2.35 |
| Optimal <br> prey size | 0.57 | 0.45 | 0.55 | 0.52 | 0.59 | 0.57 | 0.54 | 0.59 | 0.62 | 0.58 |
| mouth size |  |  |  |  |  |  |  |  |  |  |

It is interesting to note that Werner (1974) found that in two species of sunfishes the optimal prey size occurs at a prey size to mouth size ratio of 0.59 regardiess of fish size. Werner (1974) also measured the prey size as the maximum depth of prey in the dorso-ventral plane.

It vill be seen from Table 60 that this ratio for Spinachia is very close to Werner's value of 0.59. The question remains as to whether this similarity is pure coincidence or whether it has a wider application. The question cannot be answered without examining more species which also show size selection.

Estimetion of critical prey size and its relationship to mouth size.
It was clear from the observations that the time a fish takes to swallow a prey is dependent not only on the absolute aize of the prey but also on the size of the prey taken previously. For example, if a small fish swallows a large prey the time taken to swallow a subsequent small prey is greater than if the small prey had been swallowed first, therefore, in order to determine the time taken to swallow prey of different sizes in different sized fish, only the prey taken as the first
choice in the first presentations were included. Fig 25 shows the mean time taken for fish to swallow the first prey in the first presentation for the smallest, medium sized and the largest fishes used in the size selection experiments. The results for 72 and 75 mm fish and $98-99 \mathrm{~mm}$ fish are combined to increase the number of observations. All four curves in Fig 25 show essentially the same pattern, namely, the time taken for a fish to swallow a prey is short at the lower end of the size range for all fishes and it does not vary greatly with the fish size. When, however, the prey reaches a critical size, the mean time for the fish to swallow the prey suddenly increases; in other words, it becomes mechanically more difficult to swallow the prey at a certain prey size. The point at which the time required to swallow the prey suddenly increased ( 8 secs. see below) was called the critical prey size. As the fish size increases, the values for critical prey size also increases. Of the four curves, the one for $72-75 \mathrm{~mm}$ Pishes is the most complete as it includes the maximum size of the proy the fish are capable of of swallowing. This curve demonstrates that over most of the preferred prey size range the time required to take prey was

Fig. 25. S. spinachia. The mean time required by the fish to swallow prey of different sizes. e) $72 \& 75 \mathrm{~mm}$, b) $98 \& 99 \mathrm{~mm}$, c) 116 mm .

Vertical arrow indicates estimated critical prey size (see text p. 193 for definition).

PREY SIZE (m)
generally < 10 seconds, whereas nearer the maximum size of prey the fish could swallow the time required increases drastically.

In three out of four cases examined in Fig 25 the time required to take prey began to increase in the region of $\geqslant 8$ secs. Therefore 8 seconds was taken as the time which determines the critical prey size. These critical sizes may be estimated from Fig 25.. . These estimates are tabulated and compared with the estimates of the maximum prey size in Table . 67.

Table ó7. Comparison of maximum and critical prey sizes
for different lengths of fish.

| Pish size (mm) | 72 | 75 | 98 | 99 | 116 | 124 |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| Maximum prey size (mm) | 18.1 | 19.0 | 24 | 24.4 | 29.5 | 31.8 |
| Critical prey size (mm) | 9 | 9 | 14 | 14 | 18 | 18 |
| Ratio of |  |  |  |  |  |  |
| fish size |  |  |  |  |  |  |
| critical prey size | 8.3 | 7.0 | 7.1 | 6.4 | 6.9 |  |

Average ratio $=7.3$

It is clear from these figures that if 8 seconds is accepted as the time which determines critical prey size then it becomes difficult for the fish to swaliow prey when their prey size exceeds approximately $1 / 7$ of the length of the fish i.e. when the ratio of fish size/critical prey size is greater than 7. Table 67 also demonstrates that maximum prey size that can be taken is much higher than critical prey size. Fig 25 shows that below the critical prey size all sizes offered to the fish are almost equally easy to take and that the time required to take these prey is independent of fish size.

Summary and discussion.
The selection of a particular prey size by a fish of a certain size is a commonly observed phenomenon in the field and the results of the food analyses demonstrated the existence of this phenomenon in Spinachia. (Fig 17 and Section I, Pig 13).

A number of theories may be suggested concerning the nature of such selection in fishes such as that the visual acuity and swimming spped may be greater in larger fish making them more successful in capturing larger prey. Por example, Blaxter \&

Jones (1967) showed that the visual acuity in herring increased with fish size. Similarly, Baerends et al. (1960) demonstrated that in trained young cichlids the ability to distinguish between 2 close stripes improved with increasing body length. Bainbridge (1958) observed a nearly linear dependence of swimming speed on body length, and, Ohlmer \& Schwarzkopff (1959) in a different species found a nearly linear relationship with the square root of body length.

Several workers have demonstrated experimentally the existence of a well-defined response to prey size. Zunini (1937) found in minnows that the selection of a food item was related to its size. Hester (1968) has demonstrated from the principles of visual mechanics that in visualfeeders such as goldfish, large objects have a higher risk of discovery, which was verified by Ware (1972) who showed that in rainbow trout larger prey evoked stronger feeding responses. Similarly 01la, Katz \& Studholme (1970) showed that in bluefish increasing the prey size produced an increase in feeding motivation.

Laboratory observations with free swimaing mysids showed
that a prey-fish size relationship similar to that found in the field could still be observed under experimental conditions. (Experiment 1). Other experiments demonstrated thet the fish could alter their average prey size within the limits of their own range of selection (Fig 18 line a) but did not take much larger prey even if it was abundant.

The laboratory experiments demonstrate that when the capture efficiency of S. spinachia is maximized by rendering different sized prey all equally available, the mean size of prey taken still varies with the fish size; the results are copparable to those found in the field.

A comparison of successive presentations indicated that increasing satiation produced more selective response to prey size. The results agree with the findings of Ivlev (1961) and Chiszar \& Windell (1973) who found a similar relationship between the degree of hunger and selectivity of fishes.

When different sized S. spinachia were examined individually, it was found that a wide range of prey size could be taken by a fish of a particular size, indicating that when prey evailability is maximum and escape mechanisms are eliminated, the fish are capable of taking larger prey
than they would normally take in the field. This suggests that while part of any size selection in S. spinachia is affected by the swimming speed and escape mechanisms of the prey, it is not completely determined by them. The prey size range of a fish could overlap vith that of a different sized fish but within the range there is a preferred region. Estiration of the maximum swalloving capacity of the mouth of Spinachia showed that the fish vere capable of swallowing whole mysids whose size vas $\frac{1}{4}$ of their total length (Table 64 ). The optimal prey size as determined from the results of Experiment 3 suggested that the fish showed highest preference for prey size around $\frac{1}{8}$ of their total length. (Table 65 ). It was therefore concluded that the size selection observed in the experiments was not a reflection of mouth size.

On the basis of these studies it appears that there is an innate tendency in $S$. spinachia for the selection of a certain size range. Smaller fish preferred smaller prey even when the difference in the availability of different sized prey vere eliminated. The range of prey size taken, however, increases under such conditions. The results
suggest that in S. spinachia prey size selection is not purely a result of prey availability or of mouth size. In the field the maximum size of prey that can be caught is determined by the ability of the fish to catch prey, so that innate size selection is affected and modified by the differences in the swimming speeds of different sized fish and prey.

## THE EPFECT OF MOVEMENT ON FEEDING OF SPINACHLA.

## Introduction

The important role of movement as a stimulus for fish which are visual feeders is well known and is commonly applied to the design of baits for catching fish. Bateson (1889) commented on the well marked response to movement in visual fishes such as wrasse and mullet. Fulton (1904) and MeKenzie (1935) similarly observed that captive cod vere strongly attracted to food falling through the water. Messters (1940) found that the movement of the food item was of decisive importance in the feeding of pike. Tester (1963) concluded from his experiments on tuna that the most
efficient baits vere the most mobile ones and movement was the most important stimulus. Differences in size, shape and colour of the baits had no significant effect on their efficiency. Brawn (1969) found that she could evoke a feeding response in captive cod by moving a fingertip along the glass front of their tank or by moving paper discs in the water.

During the preliminary observations on the general feeding behaviour of Spinachia it was noticed that moving particles and air bubbles would often evoke a feeding response such as fixating, approaching the objects and, sometimes attack, ingestion and ejection. Preliminary observations also showed that moving palatable prey were preferred in all instances to non-moving palatable prey. Also, if the fish, after being kept for sometime on palatable non-moving food such as chopped mussel gonads, were offored unfamiliar moving prey such as adult Artemia with their usual food, they still showed a clear preference for the moving food.

When Artemia vere presented for the first time with freshly killed mysids to which the fish were accustomed, artemia
were taken preferentially. These and similar observations strongly suggested that govement was likely to be a very inportant visual stimulus initiating feedińg in Spinachia.

All the findings of previous workers and the results of preliminary observations on feeding of Spinachia point to the significance of covement in the feeding behaviour of visual fishes. In viev of this, a knowledge of the responses to movement in Spinachia was considered to be of some value in the analysis of factors affecting food selection. A study of the effects of movement on feeding of Spinachia was therefore undertaken.

The study aimed to answer four questions: (1) Is moving food taken in preference to stationary food and are there any differences in responses shown to food moring at different speeds?
(2) How does the movement affect the feeding response and vat changes, if any, does it cause in the feoding sequence?
(3) Are there any differences in responses to prey moving with different types of movement?
(4) What are the relative strengths of two faeding stimuli, size and movement?
Table 69. The number of prey taken ns first, second third and fourth choices at 5 speeds.

The effect of movement on the response to prey.
The aim of the first pari of the experiments was to show whether or not moving food was taken in preference to stationary food.

Six fishes, varying in size between 93 to 124 mm were used. They vere kept singly in the glass tanks of $47 \times 31 \times$ 31 cm used in the size selection experiments. The arrangenent of tanks and physical conditions such as light temperature were as before (see p 171). The results were recorded on a tape recorder for later analysis. Neomysis integer were used as food in these experiments.

The food vas presented to the fish as a set. The apparatus consisted of a 40 cm long, 5 cm wide flat piece of perspex to vhich transparent glass tubes could be attached at required intervals. An electric motor vas attached $\ddagger$ way along the perspex strip and a 15 cm piece of perspex rod was then attached to the motor apindle. The speed of the motor could be varied between 0 and $3.9 \mathrm{~cm} / \mathrm{sec}$ by means of a variable power supply.

As in the size selection experiments, live mysids were suspended at the end of transparent tubes of 1 na in diameter, by fishing line.

Two tubes with suspended mysids were arranged on the main perspex frame at 5 cm intervals, these held the stationary food. inother two tubes were attached to the arms of the movable piece of perspex, -separated by 10 cms so that when the motor was switched on, a smooth directional movement of the food could be sustained in a circular orbit of 31 cm . All four mysids, both moving and stationary were kepr at the same height.

Four mysids of the same size were presented to the fish at each presentation. The size of the food offered to different fishes was determined according to the optimal prey size in the size selection experiments. (See Table 65.).. The size range of the food offered to each fish was kept constant throughout the experiments.

The following prey size ranges were used for each fish (Table 68).

Table 68. The food size ranges offered to the fishes of varying lengths in the movement experiments.

| Fish size (mon) | 93 | 98 | 99 | 110 | 116 | 124 |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Food size range |  |  |  |  |  |  |
| offered (ロa) | $10-12$ | $12-14$ | $12-14$ | $14-16$ | $16-18$ | $16-18$ |

The first few observations with speeds from 0 to $3.9 \mathrm{~cm} / \mathrm{sec}$ showed that the initiation of a feeding response for moving prey vas earlier at some speeds than others, suggesting the fish responded differently to different speeds.

Pive different speeds were used to test the differences in response to varying speed. At each presentation two moving and two stationary mysids of the same size, all equally visible, were offered to each fish and the sequence in which the prey were taken recorded. Observations began after a 24 h deprivation period and continued until the fish stopped feeding.

Experiment 4 was designedtio determine whether moving food provided a stronger stimulus for feeding than
stationary food when palatability, size, colour, shape and availability of prey were the same.

The preference for stationary or moving food was determined by considering the order of choice. Pollowing the same argument used in the size selection experiments; when four prey, two moving two stationary, otherwise equal in other visual characteristics were available, the first two choices would indicate whether or not a preference for any state existed. That is, if moving and stationary prey were taken indiscriminately the ratio of first and second choices to third and fourth choices would not differ greatly from 1.

Table 69 shows the number of prey taken as first, second, third and fourth choices at five different speeds for six fishes.

The results indicated that at all speeds above $0.2 \mathrm{~cm} / \mathrm{sec}$ first and second choices differed significantly from third and fourth choices, that is, above $0.2 \mathrm{~cm} / \mathrm{sec}$ there was always preference for the moving food. Moving prey were usually taken first and stationary prey later.

The number of times when moving food was taken as third and fourth choices i.e. incidents of no selection for movement
was low in all cases between $1.0-3.9 \mathrm{~cm} / \mathrm{sec}$ but was lowest at $2.9 \mathrm{~cm} / \mathrm{sec}$.

Table . 70 . compares the preference (measured as the sum of first and second choices) shown for moving and stationary food at different speeds by means of the $X^{2}$ test. A clear selection for the moving food is evident between 1.0 and $3.9 \mathrm{~cm} / \mathrm{sec}$, the highesit preference for movement being shown at $2.9 \mathrm{~cm} / \mathrm{sec}$.

In Fig 26 the percentage of moving prey taken as first and second choices are plotted against speed. It was found that the responses to movement increased from $1 \mathrm{~cm} / \mathrm{sec}$ up to $2.9 \mathrm{~cm} / \mathrm{sec}$ then decreased slightly at $3.9 \mathrm{~cm} / \mathrm{sec}$ bui still remained at a high level. Because of the limitation of motor it was not possible to test the responses to higher speeds.

Table 71 . gives the results for the comparison of responses to prey moving at different speeds. The first and second choices which were used as the indicators for preference were summed for moving and stationary prey at each speed. The differences in responses to moving and stationary prey between varying speeds than were compared

| $X^{2}$ values for the comparisor of responses shown to prey moving at different speed <br> * $\mathrm{p}<0.01$ <br> ** $\mathrm{p}<0.001$ |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |

|  |

by the $x^{2}$ test.
The $\chi^{2}$ values show that the responses to prey moving Fery slowly with a speed of $0.2 \mathrm{~cm} / \mathrm{sec}$ were significantly different from the responses shown to prey moving at higher speeds, which means that prey moving at the lowest speed were hardly perceived as moving prey. When the prey speed reached $1 \mathrm{~cm} / \mathrm{sec}$ however, there was a considerable increase in the selection of moving prey. As the speed increased further, the preference for moving food became more marked but when the speed of prey reached $3.9 \mathrm{~cm} / \mathrm{sec}$ a slight drop in the responses to movement were observed. This drop suggested that the optimal speed has already been reached.

The number of responses to food moving at $1 \mathrm{~cm} / \mathrm{sec}$ did not differ markedly from prey moving at $1.9 \mathrm{~cm} / \mathrm{sec}$ or 3.9 ca/sec but vas significantly different from responses shown to prey moving with the optimal speed of $2.9 \mathrm{~cm} / \mathrm{sec}$.

The number of responses to prey moving with a speed of $1.9 \mathrm{~cm} / \mathrm{sec}$ were not significantly different from those moving ${ }^{*}$ with speeds of $2.9 \mathrm{~cm} / \mathrm{sec}$ or $3.9 \mathrm{~cm} / \mathrm{sec}$. Also no difference was found between the number of responses shown
to $2.9 \mathrm{~cm} / \mathrm{sec}$ prey speed and $3.9 \mathrm{~cm} / \mathrm{sec}$ speed.
This analysis showed that although the difference in responses to stationary and moving prey wás maximum at $2.9 \mathrm{~cm} / \mathrm{sec}$; the increase in preference for movement after $1.9 \mathrm{~cm} / \mathrm{sec}$ was not significant. After the critical speed of $1 \mathrm{~cm} / \mathrm{sec}$ was exceeded, movement of the prey was perceived and moving prey was selected.

The effect of movement on the feeding sequence.
The purpose of the next set of experiments was to determine the degree and the type of change in feeding responses brought about by movement. From the time measurements with stationary prey it was known that when a fish was offered a mysid of optimal size after 24 hr food deprivation, feeding was completed within 8 secs. ( $\mathrm{Pif}_{\mathrm{f}}$ 25). In these experiments (Experiment 5) single mysids were attached to the movable arm of the motor and offered to the fish as stationary food. Once again optimal prey sizes were used for each fish. The presentation of stationary food continued until the fish did not complete the feeding sequence (i.e. did not swallow the prey) within the first
minute. All responses to prey were recorded. The motor was then switched on to nove the uneaten food at a speed which was known to produce the greatest response ( $2.9 \mathrm{~cm} / \mathrm{sec}$ ) and any changes occurring in the feeding response were recorded. After this another stationary food was offered and if uneaten within a minute was moved once again, noting any changes in responses and so on. The observations ended when the fish showed no interest to the same food in both moving and stationary states. In this way the changes in the nature of the feeding responses induced by movement coulc be assessed.

A control experiment (Experiment 6) was then performed to test whether the responses to movement could be produced in the absence of food, that is when no visual clues from prey were available. After the initial deprivation period the fishes were first shown the same stationary glass tubes and responses, if any, were recorded. The tubes were then moved at the optimal speed of $2.9 \mathrm{~cm} / \mathrm{sec}$ and any further responses to the moving tubes were noted.

The number of changes in feeding responses brought about by movement of food are given in Table 72. As mentioned
Table 72 The number and type of changes in the feeding responses caused by the movement of prey.

previously on 3.158 a completed feeding response consisted of the basic
$0 \rightarrow \mathrm{PI} \rightarrow \mathrm{AP} \rightarrow \mathrm{AT}-\mathrm{GR} \rightarrow \mathrm{I} \rightarrow \mathrm{SH}^{*}$ sequence with free swiming prey. (Fig. 16). By using mysids of optimal size aziached to the tubes, the necessity for orientation was eliminated and $G R \rightarrow I \longrightarrow S W$ stages occurred simultaneously as one step; the feeding sequence was therefore reduced to four stages; PI $\rightarrow \mathrm{AP} \rightarrow \mathrm{AT} \rightarrow \mathrm{SW}$.

Any changes in the stages that occurred towards the completion of the feeding were recorded as positive changes and those frog an advanced stage such as attack to initial stages ( $A P, P 1$ ) were considered negative changes.

The total number of positive changes caused by movement were found to be significantly higher than no changes, negative changes and the sum of the latter two when compared by a $X^{2}$ test. $X^{2}$ values for these tests were $11.23,40.01$ and 4.94 respectively.

The movecent of the prey induced positive feeding responses in $61 \%$ of cases. The proportion of no changes were. $30 \%$ and negative changes $9 \%$.

When the rotal number of positive changes are considered,
the highest number of positive changes were found to occur between the stage of fixating when prey was stationary and swallowing if moved. The proportion of changes from attack to swallow and Fixate to Approach were also high.

It has been mentioned in the general description of feeding behaviour ( p 158 ) that as the fish gets less hungry the feeding chain stops at earlier stages. By this criterion the observations in the lowest row of the Table 72 where the responses to stationary prey stopped at AT level corresponds to a higher hunger level of the fishes and observations in the first row where the responses to stationary prey stopped at P1 stage to a lower hunger level. In general, the motivation necessary to induce the fish to approach a prey must be stronger than that necessary to fixate and similarly the stimulus to induce attack must be stronger than that necessary to approach. Therefore it can be assumed that the intensity of responses increases from F1 to SW i.e.,

$$
\mathrm{F} 1<\mathrm{P} 1 \rightarrow \mathrm{AP}<\mathrm{F} 1 \rightarrow \mathrm{AP} \rightarrow \mathrm{AT}<\mathrm{F} 1 \rightarrow \mathrm{AP} \rightarrow \mathrm{AT} \rightarrow \mathrm{SW}
$$

The fact that the highest proportion of positive changes at a lower hunger level was from F1 stage to the completion
of feeding and not simply to AP stage indicates that the movement of prey must provide a very strong stimulus for further feeding.

The highest number of no changes were recorded at Fixate stage which was a reflection of a high degree of satiation. The number of no changes at Approach stage were also high but they were relatively few at an advanced feeding stage such as Attack. The number of no changes increased as the hunger level of the fishes decreased.

The total number of negative changes was very low. They mostly consisted of fish approaching the food when stationary and fixating only if moved, indicating once agein a bigh satiation level.

The number and type of changes and no changes when no visual stimuli from prey were present are given in Table 73.

The total number of no changes in this case were found to be significantly higher than number of positive changes brought about by movement. $\left(X^{2}=5.03\right.$, significant at $5 \%$ level).

The highest number of positive changes took place
Table 73 . The number and type of changes in feeding responses cansed by movement of tubes only.
(Control experiment).

#### Abstract

between stages Fixate and Approach which showed that the movement alone did not stimulate feeding as strongly as movement and prey. Only in a relatively few number of cases did movepent promote the feeding response as far as the attack stぁ弓e.

The number of no changes were highest at P1-F1 stage, that is the fish mostly looked at the tubes both when stationary and moving and showed no further response. The perceñage of no chmaces at the attack stage was lowest. No negative changes were found in these observations, i.e., after approaching or attacking a stationary tube, the fish showed either the same response or advanced to the next stage in the feeding sequence.

## The effect of the type of movement on the feeding response and sequence.

The object of the next set of observations was to determine the fishes responses to prey with different types of movement at a high satiation level. The effects of two types of movemant, directional and vibratory were tested.

The fishes vere first fed on stationary mysids. When
the feeding stopped they were offered moving prey of the same size. In directional movement a single prey was moved linearly in front of the fish at a speed of $3 \mathrm{~cm} / \mathrm{sec}$ and whether or not the fish responded was recorded (Experiment 7). To test the effect of vibratory movement, a glass tube with a prey suspended from its end was attached to a set used in the size selection experiments and was placed at a distance of 20 cm facing the fish. It was then vibrated by moving it 1 cm backwards and forwards 7 times/sec. Any resnonses show to prey were recorded. (Experiment 8). Table 74 summarises the results for responses shown to directional and vibratory movement of prey at a high satiation level. Forty four and forty two observations were nade for each type of movement. The figures in Table 74 shov that if only the number of positive changes and not the types of changes are considered, the number of feeding responses induced by each type of movement did not differ significantly ( $X^{2}$ value for the comparison of the number of positive changes evoked by directional and vibratory movement was 0.36).

Also the number of responses shown to moving prey were
Table 74 .. The number and type of responses shown to prey with directional and vibratory movement
at a high satiation level.

| Type of <br> movement | Directional |  |  |  | Vibratory |  |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Type of <br> changes | F1 to AP | F1 to AT | F1 to SW | Total <br> positive <br> changes | Total <br> no <br> changes | F1 to AP | F1 to AT | F1 to SW | Total <br> positive <br> changes | Total <br> no <br> changes |
| Number | 21 | 1 | 2 | 24 | 20 | 13 | 4 | 3 | 20 | 22 |
| $\%$ | 88 | 4 | 8 | 54 | 46 | 65 | 20 | 15 | 48 | 52 |

not significantly different from the number of no responses (no changes) in each case. ( $X^{2}$ values were 0.36 for directional movement and 0.09 for vibratory movement). This suggested that at a very high satiation level, movement did not provide a high feeding motivation and this was probably independent of the type of movement of prey.

If the proportion of different type of responses evoked by each type of movement were examined, most of the responses were found to take place between Fi $\rightarrow$ AP stages for both types of movement which was likely to be a reflection of very low hunger level of the fishes.

The proportion of responses which advanced further to AT and $S W$ stages were low in both cases but were higher in vibratory movement than directional movement. This could imply although the total number of responses induced by each type of movement were not different, vibratory movement could affect the feeding more strongly than smooth directional movement. However, the number of responses at AT, SW stages are too low to reach firm conclusions.

Lastly the relationship between the two feeding stimuli, movement and prey size was investigated. Two fishes of 93 and 124 mm total lengtin were used in these observations. (Experiment 9).

At each observation the fish were offered two stationary prey of preferred size and two moving prey within the size range that could be salaen but would have been taken secondarily if stationgry.

It was known from the size selection experiments (Experiment 3) that when stationary prey was used 03 mm Pish preferred a size range of 7.5 to 15.5 mm (with a peak at 11.5 mm ) to larger prey and 124 m fish preferred a size range of 15.5 to 23.5 mm (with a peak et 17.5 mm ) to smaller prey. In Experiment 9 the 93 mm Pish was presented simultaneously with a set of stationary near-optimum size prey (10-12 mm) and a set of moving above-optimum size prey (17-19). The moving prey was rotated at a speed of $2.9 \mathrm{~cm} /$ sec. The same size ranges were used for 124 mm fish, this time keeping the large prey stationary and the smaller prey
moving. The number of times each prey size group were taken as first, second, third and last choices was recorded.

The results of Experiment 4 demonstrated that moving prey were chosen in preference to the same sized stationary prey. In Experiment 9 prey of preferred size were offered as the stationary prey and secondarily selected size as the moving prey. There were two possibilities (1) If the effects of either positive stimulus did not overrule the effect of another, no preference would be shown for either of them, i.e., the number of prey taken as first, second, third or fourth choices would not differ significantly in both moving and preferred sized prey groups. (2) If preference for movement was stronger than preference for size, then the number of moving prey taken as first and second choices would be significantly higher than the number of first and second choices of preferred (stationary) pray size.

The results of Experiment 9 are tabulated in Table 75 for each fish. The first thing that is apparent from Table 75 . is that the pattern of responses shown to moving

or preferred sized prey remained the same in all presentations for each fish i.e., if there was a selection for movement or size, it did not alter with satiation or the fish size.

When the data and the sums of individual choices are considered, the number of first choices for movement were found to be significantly higher than-the number of first choices for size in both fishes. ( $x^{2}=9.68, p<0.01$; $X^{\mathbf{2}^{2}}=15.08, p<0.001$ for the 93 mm and 124 mm fish respectively). These results indicated that initial preference was shown for movement and not for the preferred prey size.

The sum of first and second choices for movement were consistently higher than the sum of first and second choices for size in all presentations for each fish, but the difference did not reach a statistically significant value in any one of them. This contrasted with the results presented in Table 70 . where, for equal sized prey moving at speeds $>1 \mathrm{~cm} / \mathrm{sec}$, the sum of first and second choices was always significantly higher than the sum of the first and second choices for stationary food. The results in prey size and moving secondarily preferred size were offered to the fish, preference for movment did not completely overrule the preference for size.

The number of second and third choices for movement did not differ significantly from the number of second and third choices for size. The number of last choices indicating the least preference was always significantly higher for size than movement. This meant that when the fish encountered moving prey of secondarily preferred size and stationary prey of preferred size, it first reacted to movement, but it did not necessarily select the remnining movinf prey second.

Table 76 shows the number of times that movenent and preferred size were taken in a particular order. For example in the moving prey group 1,2 means the moving prey were taken as first nnd second choices; 1,3 first and third choices; 1,4 first and last choices and so on. The figures verify the seme points shown in Table 75 namely that in all presentations most of the moving prey were taken either as first and second $(1,2)$ or first and third $(1,3)$
Table 76 . Number and times the movement nnd preferred size taken in n particular order for two fish

choices. Most of the preferred sized food were taken as second and fourth (2,4); second and third (2,3) and third and fourth $(3,4)$ choices. Once again the initial selection for movement is clear.

Summery and discussion : Experiments 4-9.
Experiment 4 demonstrated that Spinachia shows a very strong preference for moving prey. Also there was a threshold speed of prey above which all moving prey were chosen in preference to stationary prey.

Experiment 5 showed that even when the hunger level was not high the movement of the prey induced further feeding. Part of this response was due to the movement of tubes holding the prey (Experiment 6) but this movement alone did not stimulate a feeding response as strongly as when prey were also available, even though the hunger level was higher than in Experiment 5.

At a very high satiation level, movement of prey could still evoke feeding responses from the fish (Experiments 7,8). but its effect on feeding was much less than that found at lower satiation levels (Experiment 5). Also, at a low hunger
level, no difference between the two types of movement was found though there kere indications that vibratory movement was more effective than directional movement. (Experiments 7, 8).

The observations on size-movement comparison (Experiment 9) showed that the fish initially responded to prey novement and not prey size and this was indeperdent of hunger levels. However, it did not completely ignore the size cue from the prey once it was in the vicinity of suitably-sized prey. The effects of size and movement were therefore additire, movement being the stronger stimulus.

The above results agree in general with those of other workers (Bateson 1889; Fulton 1904; McKenzie 1935; Brown 1969) in that movement is indeed a strong feeding stimulus to visual fish which feed on moving prey. Tester (1963) found in tuna that the effect of the movement of prey completely overruled the other external features of prey. In Spinachia although movement has priority, the size of the prey is still important. This suggests that food selection in Spinachia is probably a result of several factors.

Introduction
Many authors hold the view that movement and size of the prey are of primary importance for feeding of visual predators. Other external prey features such as colour and shape are generally thought to be of secondary importance. The primary importance of prey movement has often been demonstrated experimentally, for example by Martin et.al. (1974) who showed the significance of prey movesent in feeding of newts. De Groot (1971) in the feeding of flatfishes, Smith (1973) in the feeding of shrikes. On the other hand, the influence of colour and shape on food selection has been well established for some fishes. Certain species react maximally to a certain colour which is usually the colour of their natural food and many marine fish are able to distinguish between the different shapes of models (Protasov 1970; Herter 1940).

It has already been mentioned in the general feeding behaviour section that Spinachia attacked mysids from the
side and swallowed them head first. Directing attacks at the head of prey is a common feature among predatory animals. The predator could react either instinctively or by experience to the specific cues associated with the head or to the anterior end of the body, that is, react to one particular portion of the body in relation to the rest of the body or to a combination of these two factors. If the head is recognised as the anterior end of the body, head discrimination could be a function of prey movement. Smith (1973) has suggested that the forward motion of body may direct the predator's attack to the foremost part of the body i.e., the head.

In addition, it was also noticed during the observations on Svinachia that when darker coloured mysids were put into the tank together with transparent mysids, the fish responded to the dark mysids first. The responses to darker coloured prey were not as frequent as the attacks to prey heads, nevertheless they suggested that mature Spinachia could discriminate between different shades.

Attacks directed at the head of the prey appeared to be a consistent feature of feeding; responses to dark
mysids also occurred quite frequently. Such observations suggested that on investigation of the relative importance of shape and shade in evoking feeding responses in Spinachia would be of some value.

Questions that arose were whether head attack was solely due to the movement of prey and if not, which cues in the head made it more attractive to the fish than other parts of the body. If the effects of shape and shade stimuli could be established, then the role of these external prey features in the selective feeding of Spinachia could be evaluated in greater detail.

## Feature of the attack on stationary musids.

The aim of the first part of the experiments was to see whether the fish would discriminate between different parts of the prey body when the prey was stationary. Neomysis integer was used as prey. (Experiment 10).

A group of mysids were kept in a glass tank for six weeks and due to colour adaptation they became opaque white in appearance. The stalked eyes vere large, black and very conspicuous in the head. The darkly pigmented stomach
under the carapace was also quite conspicuous from the dorsal view in the anterior third of the body. Tro rows of dark pigment bands extended from head t'o tail. The pigmentation at the tail segments was slight. The overall nicture of the mysid consisted of a darker head region tapering towards a lighter mid-part and tail.

Single live mysids within the predators preferred size range were offered to the $f i s h$, held stationary by attaching them to the glass tubes used in the size selection experiments. The mysids were suspended from the tubes in such a way that the fish have a broadside view. Five fishes of $72,75,102,106,110 \mathrm{~mm}$ total length were used in these experiments. The number of times the fishes attacked the various parts of the mysid body are given in Table 77..

The results showed that the number of attacks directed at the hond vere very significantly higher than the number of attacks made to the middle of body and to tail. They were also significently hipher than the sum of attacks to middle and tail corbined. It may be concluded therefore the head was clearly differentinted from the rest of the

Table 7 . Comparison of the regions of attack of mysids
$A=$ nugber of attacks made on different body regions
$B=X^{2}$ and $\rho$ values for comparison of attacks between different
body regions.
$x^{2}$ rive at $p=0.001$ level is 10.83 .

body, even when stationary.
The number of attacks made to the middle region of the body did not differ significantly from those made to tail. The fact the: the giddle part was not differentiated from the tail which is :he posterior end of the body showed that head selection cocis not be solely based on recognising the ends of the body. in $\equiv$ stationary prey.

The possible cues present in the mysid head which could
contribute towards the recognition of this part of the body as head when stationary are:

1. Overall shape of the head region together with shape of antennae, eyes, carapace and legs;
2. Inickness of the head region compared to tail;
3. Overall differences in shade caused by the black eyes, dark alimentary tract, pigmentation at the base of the legs and opaqueness of the head region in contrast to the transparency of tail;
4. Movements of legs, antennae.

The head recognition would be due to the combined effects of 1 to 4. Por example, the head could be distinguished as the thicker, darker end of the body with moving extensions.

Comparisons between body regions and colour.
In the second set of experiments (Experiment 11)
Praunus flexuosus vas used as prey because Praunus was found to show a bigher degree of colour adaptation than Zeomysis

A group of Praunus were kept in white tanks to reduce their colour as mach as possible. When colour adaptation
was maximum only the black eyes, alimentary tract and the pigments at the base of the legs contrasted with the remaining part of the body which was uniformly transparent.

A second group of mysids were kept in black tanks to darken their colour maximally. Even when they were at their darkest, the contrast between the black eyes and the rest of the body was still noticeable. In order to eliminate this contrast the whole animal was darkened with finely powdered animal carbon. Mysids were rolled in the powder until the whole body acquired a very darkly pigmented appearance.

A complete set of comparisons were carried out between the various combinations of head, tail, black and white. (Experiment 11).

The fish were presented with two choices at time, a white head and black head for example and the number of times each one was selected were recorded.

The portions offered were kept equal in length but although the head of a smaller mysid was offered together with the tail of a larger mysid in order to equalise the
thickness of the parts, small differences in the thickness of the head and tail still existed.

Head portions and whole animals were not compared because although their length could be equal, their thickness could never be, and vice versa.

By using dead animals and as near as possible equally sized portions, the effects of thickness and moving parts, such as legs, were eliminated from the list of possible cues for the recognition of head given earlier. The observations, therefore should test the effect of shape and shade.

Table . 78 gives the number of times that heads, tails, black and white were selected and the total number of of observations in each comparison.

At each comparison it was assumed that there was no selection between different parts and colours offered, the null hypothesis being that equal numbers of each choice were likely to be taken in each set of observations. If the null hypothesis was correct then the number of choices in each category for each comparison would not differ significantly.
Table 78 - Comparison of the choice between prey body regions and colour.

| 10 | $\begin{gathered} \text { White whole } \\ 49 \end{gathered}$ | $\begin{gathered} \text { White tail } \\ 29 \\ \hline \end{gathered}$ | 78 | 4.63 | < 0.05 |
| 11 | $\underset{41}{\text { Black whole }}$ | $\underset{26}{\text { Black tail }}$ | 67 | 3.36 | $>0.05$ |

On the basis of the results given in Table 78 it appeared that the head was dominant to tail and black was dominant to white. The degree to which each characteristic was selected seemed to depend on the presence and absence of other characteristics. For example, black heads and black whole animals were selected in preference to white head and white whele animals but this selection for black colour was not as strong when only black and white tails were present.

A scheme wes devised to describe the selection mechanisms that were thought to be operating. Arbitrary cue strengths were chosen for each body part and colour. It was assumed that the order of dominance was Black $>$ Head $>$ White $>$ Tail. Black was given a cué strength of 4 , head 3, white 2, tail 1.

Using these arbitrary cue strengths it was possible to predict the outcome of any comparison by comparing the difference in scores of the two choices offered, the choice with the higher score of cue strength being preferred. For example a black head (score $4+3=7$ ) should be taken more often than a white tail (score: $2+1=3$ ) and so on.

Table 79 lists the comparisons and their predicted outcones.

In 8 out of 11 comparisons the actual outcomes matched the predictions but there were three outcomes which did not agree with the predictions.

First, if black colour was always dominant to white and was independent of the part of the body, it would have been expected that black tails would have been preferred to white tails. Although the number of black tails taken was higher than the number of white tails, the difference was not statistically significant. (Table 79, , comparison 3).

Secondly, when white whole animals were compared with black tails, although whole animals, which contained the preferred characteristic "head", were taken in higher numbers the difference once again was not significant (Table 79, Comparison 9).

Thirdly, when black whole animals with the preferred "head" cue vere compared with black tails, higher number of whole animals were taken than the tails but the difference did not reach the 5\% significance level. (Table 79, Comperison 11.
Table 79 . Comparison of the actual and predicted outcomes of prey choices based on the differential
"cue strength" hypothesis. (See p ).

| 10 | $\begin{gathered} \text { White (Head }+ \text { tail) } \\ 2+3+1 \\ =6 \end{gathered}$ | $\begin{aligned} & \text { White tail } \\ & \begin{array}{r} 2+1 \\ =3 \end{array} \end{aligned}$ | 3 | WHT > WT | $\checkmark$ |
| 11 | $\begin{gathered} \text { Black (Head }+ \text { tail) } \\ 4+3+1 \\ =8 \end{gathered}$ | $\begin{aligned} & \text { Black tail } \\ & \begin{array}{r} 4+1 \\ =5 \end{array} \end{aligned}$ | 3 | BHT > ${ }^{\text {BT }}$ | - x |

The overall trend of the results suggested that the scheme of black being dominant to white and head dominant to tail was probably correct, although the three wrong predictions may indicate that the relative strengths of different cues were slightly different from those alloceted. For example, the actual strength of the black cue was not one cue strength unit more than the strength of the head, twice the strength of white or four times the strength of the tail cue. Also the effect of combining a number of sion stimuli may not necessarily be simply additive in en aritheetical sense.

The nonsignificant differences obtained in comparison of whole animals with tails could also be partly due to the unequality of the thickness of portions. A smaller. whole animal was presented together with the tail of a larger mysid to equalise the parts as much as possible, but there still could be differences in the actual thickness of the two choices. If one of the recognisable characteristics of head was its thickness, a thicker tail could have some of the attractiveness of head, hence a greater number of tails would be selected than in straightforward head and tail
comparisons. In support of this view, it was noticed that the fish attacked the anterior, thickest part of the tail portion throughout the observations.

Comparison of size and colour stimuli.
It has been aentioned above that read and whole animal comparisons were not attempted when testing the effect of colour and shape, because the thickness and length of the two portions could never be equalised. They were used in comparison of the relative stimulus strengths of size and colour. (Experiment 12).

Two fishes of 72 mand 102 mm total length were used. Each fish was presented with head portions and whole mysids of the same thickness but of different lengths and alternate colours. The length of the head portion was 7 mm and of the whole mysid 14 mm . Fig 20 Fig 21. show that the length of the head portion vas within the optimal size range of 72 fish while that of the whole mysid was secondarily selected. Similerly the size of whole mysid was optimal for 102 mm fish and head portion was of secondarily selected size. The number of times head and whole animals
were selected were recorded. The null hypothesis here was that an equal number of each choice vere likely to be taken in each set of observations by each fish. The results of the outcomes are tabulated in Table 80.

Table 80. Comparison of the choice bezween prey colour and size for two indivicual fishes.

| Comparison <br> Number | $\underset{(\operatorname{man})}{\text { Fish size }}$ | Type of Comparison | Number of Tests | $x^{2}$ | P |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | 72 | White Head Black thole 24 12 | 36 | 4.0 | $<0.05$ |
| 2 | 72 | Black Head in三ie inole <br> ' 22 <br> 8 | 30 | 6.53 | <0.025 |
| 3 | 102 | White Head Black ihole | 67 | 9.32 | <0.005 |
| 4 | 102 | Black Head White whole <br> 14 <br> 27 | 41 | 4.1 | <0.05 |

The comparisons of size and blaci, sinite colour were found to be significantly different in all cases and the null
hypothesis was rejected.
The results show that both fishes in each set of comparisons took a significantly higher number of their preferred size, regardless of its colour. This showed that size stimulus was stronger than the stimulus provided by colour.

Earlier comparisons suggested that black was a stronger stimulus than white (Table 78).. For both fishes $\boldsymbol{Z}^{2}$ values of the comparisons where the preferred sized food colour was black were higher than when it was white. (Table 80 comparisons 2, 3). This may indicate the additive nature of colour and size stimuli; which suggests that if a food is both of preferred size and black, the selection for it is stronger than if it is of preferred size and white.

GENERAL SUMMARY AND DISCUSSION OP THE EXTERRAL PACTORS
AFFECTING PREY SELECTION BY SPINACHLA.

The results of Experiments 1-3 deomonstrated that size cue of prey was significant in the selection of food by Spinachia. For each Pish size, an optimal prey size range
was found. (Experiment 3). This preferred range became more marked as the fish became more satiated. The trend of increasing selection for size with a high degree of satiation was demonstrated both when the number of negative responses were considered (Fig 20, Taole 61 ) and when the percentage of first and second choices was examined (Fig 21 , Table 62). Meesters (1940) mentioned in his work with Phoxinus laevis that when the fish were hungry, they preferred bigger objects, and on the whole, they were less selective. Ivlev (1961), Protasov (1968), Ware (1972) similarly hold the view that fish become more selective with regards to prey as the hunger level decreases. The earliest experimental evidence for the selection of a preferred size is given by Herter (1929).' He trained Phoxinus laevis to respond to small and large shapes and found that the response to smaller objects was highest. He did not measure the responses to a graded series of sizes so that the smaller sizehis fishes selected was presumably closer to their optimal size. Unfortunately he does not give the size of the preferred shape or of the fish which would enable us to work out the relationship between the fish size and preferred size. His
observations do, however, suggest the presence of an optimal size in this fish. Zunini (1937) similarly demonstrated experimentally in Phoxinus laevis, by offering the fish wax globules of varying size, that the size of object selecter depended on the size of the fish.

No optimal prey size determinations are found in the literature until quite recently. Werner \& Hall (1974) showed the existence of an optimal prey size in blugill sunfish under experimental conditions and discussed size selection in relation to searching and handing time.

Experiments 4-9 examined the importance of movement as a feeding stimulus in Spinachia. When the fishes were hungry, moving prey was always preferred to stationary prey. Also when the hungér level was lower, movement provided strong motivation for further feeding and this was apparent from the analysis of feeding stages, but when the satiation was complete, wovement of food no longer stimulated feeding.

Meesters (1940) showed that in pike, moving prey stimulated feeding much more strongly than stationary prey. Tester (1963) showed the importance of uovement of prey
in his research into bait selection by tuna. Brawn (1969) found for cod that a feeding response could be evoked by moving inedible objects. Experiments with Spinachia using moving tubes without prey (Experiment 6) showed that although movement alone could evoke feeding responses, they were not as strong as movement and prey combined, suggesting that visual cues from the prey as well as movement were important in food selection. In this respect Spinachia is different from tuns in which Tester (1963) showed that size, shape and colour of bait did not affect the feeding response.

Experiments with moving prey showed that in Spinachia there was an optimal speed of prey movement. This is similar to Meesters (1940) findings with minnows. He found that the number of attacks made on a wavy thread moving at different speeds was dependent upon the frequency of the thread's movement, up to a maximum of 1.5 movement/sec. This optimal speed was similar to the frequency of movement of the fishes natural prey (Enchytraeus). When the Irequency of movement was higher than $1.5 \mathrm{mov} / \mathrm{sec}$, the attack rate dropped. In Spinachia the highest number of responses were shown to prey moving at $2.9 \mathrm{~cm} / \mathrm{sec}$. The
swimming speed of their natural prey, such as amphipods and mysids, were not measured but optimum speed to which the fish responded most strongly is probably related to the speed of their natural prey.

Experiments 4 ani 5 denonstrated the importance of size and movement of prey in evoking feeding responses. A comparison of the relative strengths of size and movement stimuli demonstrated that the fish responded initially to movement and moving prey was selected first, regardless of it's size. It was also found that the movement of prey, though dominant, did not completely overrule the size stimulus. (Experiment 9).

General observations on the feeding behaviour of Spinachia showed that attacks to the head of moving prey were much more frequent than attacks to any other part of the body. Meesters (1940) similarly observed that pike usually attacked roach at the head end. Observations vith stationary prey in Soinaehia (Experiment 10) demonstrated that head attack persisted even when the prey was stationary and thus could not be solely a result of prey movement. This suggested the possibility of the existence
of shape reconition in Spinachia which might be combined with shade recosaition as the dark eyes of the prey provided a shar? contrast to the colour of the body. Zunini (1937) found that Phoxinus laevis preferred objects with irregular surf̂aces more than those with flat smooth surfaces. If such recogizion applied to other fishes it could provide another explanazion for the recognition of head portion of prey by Spinachia. The tails of the mysids used as prey have smooth flat strfaces whereas the surface of the head portion is more irregilar with extensions and protrusions such as antennae, legs and eyes. Hager (1938) found that when both Phoxinus laeris and Eupomotis gibbosus were presented with flat surfaces of the same size and shape, but one with uniform colour and the other divided into different patterns such as squares, the plain surface was much less preferred than the one divided into patterns. If such a preference also applies $T=$ Sjinachia it could also contribute towards explanation of the selection of mysid heads which, as well as being more i-regular in structure, have a less uniform colour than the tail. When different body portions of same colour were offered to Spinachig, it was found that head was
preferred to tail. Similarly black was found to be dominant to white. The outcome of comparisons of different body parts with different shades suggested a relationship between head, tail and black, white as follows:

Black $>$ Head $>$ hite $>$ Tail
The results suggested that shape and shade stimuli were possibly additive but not in a straight-forward arithmetical sense. This phenomenon may be another case of the general principal of the "heterogeneous summation" of stimuli. (Hinde, 1966).

The selection of black colour over white is to be expected as the black colour increases the contrast of prey with the environment; but black preference orer white does not appear to be general. Herter (1953) found among six species of fish he examined four selected white in preference to black, and two preferred black to white. Furthermore he found in some specie: that this colour selection could be modified by association with other fish; in other words, those fishes which selected black over white individually, after being kept for a month or so with fish which selected white over black changed their preference. Black preference persisted
in one species even when kept with fishes which preferred white. In another set of observations he offered Phoxinus laevis black and white shapes on contrasting backgrounds and found that white was selected more when the background of aquarium was black. This suggests that the contrast between the prey and background is more important than the actual colour. Hager (1938) similarly found in Eupomotis gibbosus L. a black square with white stripes was preferred to a white square with black stripes as white on black background offered a stronger contrast than black stripes on white background.

The relative strengths of colour and size stimuli vere tested in Spinschis by offering the fish black and white prey of preferred and secondarily preferred size. (Experiment 12). It was found that regardless of colour, both fishes of different size, selected their preferred size, whether it was black or white. When the food was both black and preferred size, the selection for it was more marked, which suggested that although size is dominant to colour, the two stimuli could be additive.

The relitive stimuli of shape and size were not compared, but as colour is a stronger stimulus than shape, and size
stronger than colour, it could be predicted that size is probably dominant to shape.

The results suggested that in Spinachia the importance of the various sign stimuli presented by prey have the following relationship
\lovement > Size > Colour > Shape (Shade) •

Meesters (1940) found that when the responses of three spined sticklebacks to a motionless wavy thread were compared with those to a motionless straight thread, the fish preferred the wavy thread, indicating shape recognition in this fish. When the straight thread was moved however, the responses to it increased up to a maximum and then declined with a further increase in the speed of movement. His results suggested that the stimulus for movement is stronger than that of shape, as well as demonstrating the presence of an optimal speed of prey movement.

Movenent, size, colour and shape of prey all contribute towards making the prey more visible to a predator, hence it can be expected that they should be significant in prey selection.

Experiment 3 clearly showed that an optimal size range exists for each fish size in Spinachia. Since a large prey is both more conspicuous and beneficial for the fish than a small one, one would not expect the selection of a particular size under experimental conditions where small and large prey were rendered equally catchable. The results showed that even with stationary prey, a small fish does not take the biggest prey it is capable of swallowing but selects a certain size. If size selection exists, it must have a practical value for the fish. Thus it is necessary to consider what benefit the fish could derive from selecting an optimal size range, for it is logical to assume that natural selection will necessarily favour those foraging patterns in a species that are most econonical.

If all prey were equally easy to find, capture and swallow; then the biggest prey will be more beneficial to fish than smaller ones i.e., the fish obtains a larger benefit (food intake) at a smaller cost (energy output); therefore the prey size which gives the smallest "cost " ratio will be most advantageous for the fish (Werner and Hall, 1974).

[^5]Table 81. Comparison of preferred prey size range and critical prey size for fishes of different sizes.

| Fish <br> size | Preferred prey size |  | range | Critical prey <br> size (mm) |
| :--- | :---: | :---: | :---: | :--- |
|  | $<5.5$ | 9.5 | 11.5 |  |
| 75 | $<5.5$ | 7.5 | 11.5 | 9.0 |
| 98 | 7.5 | 11.5 | 15.5 | 14.0 |
| 99 | 7.5 | 13.5 | 15.5 | 14.0 |
| 116 | 13.5 | 17.5 | 21.5 | 18 |
| 124 | 13.5 | 17.5 | 23.5 | 18 |

It will be seen from, Table 81 that optimum prey size and the estimated critical prey size are in close agreement and in all cases the critical prey size lies well within the preferred range. Hence the hypothesis put forward above to account for the existence of an optimal prey size may be considered valid.

## Introduction

The results of the gut content analyses showed $P$. gunnellus in the field fed primarily on small crustacean and, like S. soinachia, amphipods were the main food item in the diet. (Tables 18, 19).

There were also indications of size related feeding heterogeneity, that is, the type of food in the fishes stomachs varied with the size of fish. This relationship between food types and fish size however, was not as well defined as in S. spinachia, but was most apparent at both ends of fish size range. For example, crabs and fish were taken by the largest fish and the importance of small crustacea such as harpacticoids in the diets of the fish increased markedly in the summer months when most fishes examined were juveniles. This suggested the possibility of prey size selection in P. gunnellus. It was not known whether the fish actively sought a prey of a certain size or whether any division of prey sizes in fish stomachs arose as a result of the fishes ability to catch and swallow prey.

The aim of the laboratory observations on P. gunnellus was to

Introduction
The results of the gut content analyses showed $P$. gunnellus in the field fed primarily on small crustacean and, like S. soinachia, amphipods were the main food item in the diet. (Tables 18, 19).

There were also indications of size related feeding heterogeneity, that is, the type of food in the fishes stomachs varied with the size of fish. This relationship between food types and fish size however, was not as well defined as in S. spinachia, but was most apparent at both ends of fish size range. For example, crabs and fish were taken by the largest fish and the importance of small crustacea such as harpacticoids in the diets of the fish increased markedly in the summer months when most fishes examined were juveniles. This suggested the possibility of prey size selection in P. gunnellus. It was not known whether the fish actively sought a prey of a certain size or whether any division of prey sizes in fish stomachs arose as a result of the fishes ability to catch and swallow prey.

The aim of the laboratory observations on $P$. gunnellus was to
determine whether or not there was an instinctive or learned preference for a particular size of prey in different sized fish.

The relationship between fish size and prey size in the laboratory. Nethods: A group of 8 fishes with a total length varying between $80-170 \mathrm{~mm}$ were used. They were caught in the field and kept in the tanks for 4-6 weeks prior to the experiments. Trials with various food items showed that they readily took a variety of food both familiar and unfamiliar such as mysids, live Artemia. chopped mussel and squid pieces. Both dead and live mysids were found to be highly palatable to the fish although the fish had difficulty in capturing the swimming mysids. Mysids were chosen as the food objects for the size selection experiments to enable a direct comparison with the results obtained with S. spinachia where live mysida vere also used as prey.

The fishes were placed in the same perspex tanks used in the Spinachia experiments. The fish were observed aingly. The physical conditions in the tanks were as described for S. spinachia. The apparatus used to offer the fish the prey of different aizes were the same as that described in pp. 172 except that to render all prey equally visible to the fish and facilitate capture, the tubes
to which prey were attached extended to the bottom of the tank. Preliminary observations showed that after the initial food deprivation period when the fish was released into the feeding chamber, it swan directly ahead to the food and apparently did not see all the four prey presented, reacting at most to two adjacent preys. This was especially true in smaller fishes. In order to enable the fish to see the prey equally, only two prey at a time were presented.

The size range of the mysids used in the observations was 4-27 mm. During the course of the experiment it became clear that the fish, particularly the larger ones, would respond to prey larger than 27 m. Since mysids larger than 27 m were not available, shrimps (Crangon crangon) were used to extend the available prey size range up to 60 mm .

At each presentation one large and one small mysid were offared to the fish and the prey to which is first responded i.e., attacked, bit off a part or swallowed was recorded. The steps before AT stage in the basic feeding chain (i.e., $P I, A P$ ) were not included as positive responses. The number of first and second choices for each 2 m prey size group were recorded.

Decription and Peeding behaviour of P．gunnellus

D．gunnellus is a bottom living fish and extremely flattened laterally．In the tanks the fish could swim both vertically and alozg ine bottom of the tank，hhen swimming，it moved its body fres sije to side in a sinusoidai wave，rather like an eel．The fiṡ rezained mostly stationary with body curled．It seemed to preä́n places where the body in the resting postion could be in maximu contact with the surface of the substrate，corners of the tare were favourite locations，then there were more than one fish in sie tank they did not choose separate corners but remained in the $\equiv$ 淢 corner．fhen searchirg fior the food，the head was dirseited forward and lifted by propping on pectoral fins，the tank area teing searched by the eyes．This lifting of the head， prozeed up on the pectoral＇fins，which was typical of the searching bet＝viour of this fish，appears to be common emong bottom feeders． Both M．scorpius and T．bubalis vere found to display pectoral fin pro：－izg in the tanks．Stickney（1973）gives a description of sifiler behaviour observed in flaz fishes．

E．zunnellus could move its eyes without head or body movミニヒエis，turning of the head from side．to side was also commonly obserred．There were sudden ourbursts of rapid swimming，the fish
would then stop, both eyes fixed binocularly on the potential food object; then make an attack towards it. The basic feeding sequence was similar to that of S. Spinachia, that is,

Fixation $\rightarrow$ Approach $\rightarrow$ Stop $\rightarrow$ Attack $\rightarrow$ Ingest.
Stopping before attacking seemed to occur core frequently than in S. spinachia. A mysid could be ingested both from head onwards or from the side, folded into two. Biting pieces from a large food item was also common. P. gunnellus was able to take food from tank surface by swimming upwards, but was more efficient when taking food from the bottom.

Yawning actirity was observed mostly in the resting position and appeared to be more frequent than in S. spinachia.

Results:
Since there vere only two choices at each presentation, the preference shown for each size group was determined by the extent to which it was selected as the first choice, i.e., the number of prey attacked first is expressed as a percentage of the total number of prey presented in that size group.

The percentege preference shown for different size groups were similar in the first and subsequent presentations. When the
number of first and second choices in the first presentations were compared by the $\chi^{2}$ test with those in the subsequent presentations in each size group, 6 out of 8 fishes showed no differences in preference between the presentations.

For the two fish that did show differences, the number of first and second choices in the first presentations were found to be different from those in following presentations at the 9 significance level in 5 out of 12 size groups examined. As the majority of the fish did not show significant differences in number of Pirst and second choices in the first and subsequent presentations, the pooling of the results for each fish was considered to be valid.

The percentage preference shown for different size groups of prey offered are given for each fish in Fig 27 and Table 82

The prey size groups above 26.5 mm correspond to observations where shrimps vere used, as it was not possible to collect mysids lerger then 27 mm . The observations suggested that the use of shrimps did not affect the pattern of responses. It was assumed that the fish continued to respond to the size of prey and not other visual clues such as colour and shape that differ from mysids.

Fig 27 shows the variation in percentage praference with

Fig. 27. p, gunnallus. The percentage preference shown for different prey size groups for 3 fishes of a) 80 mm , b) 120 mm , c) 155 mm .

Prey sizes are in 2 mm groups up to 36 mm , thereafter they are in 5 mm groups. The dotted lines on the right hand part of the figures indicate the change in prey from mysids to shrimps.

Table 82. The relationship between the percentage preference and different prey size groups. The top half of the table refers to mysids, the bottom half to shrimps.

different sizes of prey in 80,120 and 155 mm fish.
The three fishes show essentially the same trend, namely, the percentage preference is low in the lower end of the size range, its values being much below the $50 \%$ level. When the prey size reaches a certain value, the percentage preference increases above the $50 \%$ level and remains high and relatively unchanged over a wide size range. As the prey size continues to increase, the percentage preference falls sharply below the $50 \%$ level once again and remains low until it finally reaches zero.

In the 80 mm fish, the percentage preference increased rapidly with prey size above 6-7 mm prey size group; remained above $60 \%$ up to $18-19 \mathrm{~mm}$, decreased sharply with a further increase in prey size and tailed off to zero at 30-31 ma.

In the 120 mm fish the percentage preference increased more gradually in the lower end of the size range, exceeding the $50 \%$ level at $12-13 \mathrm{~mm}$. It remained high up to 27 mm , then fell sharply at 28-29 mm.

The 155 mm fish showed the same plateau pattern as the 80 mm Pish where the percentage preference was low at both the lower and higher ends of the size range. Between these low preference zones, there was a well defined high preference region which
remained relēirely unchanged．

It will छe seen from the data in Table 82 that the remaining fire fishes exhibited the same pattern，this being most clearly $\dot{C} \in m \in a s t r a t e d$ by the $110,135,170 \mathrm{~mm}$ fishes．

In the $\mathrm{j}_{\mathrm{F}}=\mathrm{Z}$ ：ish the percentage preference for the smallest prey size grou〕 cîfered， $4-5 \mathrm{~mm}$ ，is above 50 ，which suggests that the higi zzezerence region starts at a lower prey size．The percentage prefezence begins to decrease after 10－11 mon prey size．

Also in $\ddagger=290$ an fish the plateau pattern is not as clearly defined as in 0 ins fishes but a size range where the percentage
 epparent．
 preference ves＝z＝sistently high for 8 fishes．The lower and upper
 Which were cossistently above $50 \%$ at both ends of the prey size range offerec．Tze lower end of the preferred size range for the

The mia：ニー Felues of the preferred prey size range increased with the $f i s=s j z \div u_{2}$ to 110 mm ．They then remained relatively

Fig. 28. P. gunnellus. The relationship between fish size and preferred prey size range. Upper and lower lines show the upper and lower limits of the preferred prey size ranges respectively. Points above the horizontal broken line are those in which shrimps instead of mysids vere used as prey.

Fig. 29. P. qunnellus. The relationship between fish size and the width of the preferred size range. The arrow on the symbol for the 5 cm fish indicates that the range is at least 7 mm .
unchanged between 110 mm and 170 mm .
The increase in the maximum values of the preferred prey size range with increasing fish length is much more consistent. It rises steadily from $10-11 \mathrm{~mm}$ for the 50 mm fish to a prey size of $34-35 \mathrm{~mm}$ for the 170 mm fish.

In Fig 29 the preferred size range is plotted against the fish size. It shows that the preferred prey size range became progressively wider as the fish size increased.

The relationshio between prey selection and prey size difference.
During the above observations it was noticed that when a large and small prey were offered, most fishes responded to the larger one first. In order to see whether this was a consistent feature, the number of times the fishes reacted to small and large prey first, whatever the absolute sizes, was summed for all presentations and the number of larger prey selected first is expressed as the percentage of the total number of small and large prey selected.

Pig 30 and Table 83 show for 8 fish the variation in percentage preferences for the larger prey with increasing difference in length between the two prey presented. The results

Table 83 The relationship between percentage preference for larger prey La prey size contrast.

correspond only to observations where mysids were used as prey and hence covered a size range of $4-27 \mathrm{~mm}$. Fig 28 shows that this range ( 23 mm ) is outside the preferred range of the threo smaller fishes of $50,80,90 \mathrm{~mm}$ total length but within the preferred range of all others.

Por the 50 mm fish the percentage preference for the larger prey was above the $50 \%$ level when the contrast between large and small prey were 2,3 and 4 mm (Table 83 ) but as the contrast increased further, the percentage preference for the larger prey decreased linearly, the smaller of the two prey offered usually being selected first. For this fish the correlation between the percentage preference for larger prey and contrast in prey aize was negative and significant at the $2 \%$ level.

The preferred prey size range of the 50 mm fish was between 4-11 mm (Fig 28 ) which was much smaller than that offered to the fish, 4-27 um. The selection of saaller prey by this fish was likely to be a result of it being offered prey which for the most part were outside its preferred range.

For the 80 mm fish the percentage paference for larger prey was above $50 \%$ level between $2-8$ mm size contrast and dropped sharply below $50 \%$ abuve 9 mm contrast. The correlation between
prey size contrast and percentage preference for larger prey was not significant between $2-8 \mathrm{~mm}$ contrast or 9-14 mm contrast. Percentage preference for larger prey was above $60 \%$ between $2 \mathbf{- 8} \mathrm{~mm}$ contrast and under $40 \%$ between $9-14 \mathrm{~mm}$ contrast. Once again it was likely that the results were affected by the offered prey size range being greater than preferred size range.

The 90 mish likewise did not show any clear relationship between the percentage preference for larger prey and prey size contrast, fluctuating between 30 and $60 \%$ over the whole range.

The remaining 5 larger fishes presented a consistent pattern. In each fish after a 2 mm conbrast, the percentage of preference for larger food was always above the $50 \%$ level i.e., as the size contrast between the prey offered continued to increase the fishes consistently responded to the larger prey first. Moreover, the results suggested that the percentage preference for the larger prey at first increased with increasing contrast, then levelled off.

Por $120,135,155$ and 170 mm fishes a positive correlation was found between the percentage preference for larger prey and prey size contrast as the difference between large and small prey increased from 2 mm to 8 mm . The correlation coefficient was significant at $p<0.01$ for all 4 fishes. As the size contrast
increased further the preference for larger prey remained unchanged. No significant correlations between the percentege preference for larger prey and prey size difference were found for 9-17 mm contrast for the same fishes.

Por the 110 mm fish, the preference for larger prey remained well above $50 \%$ level for 2 mm size contrast but did not show an initial increase with increasing contrast as in the case of 120 , 135, 155 and 170 mm fishes. The correlation coefficient between the percentage preference for larger prey and increasing contrast was found to be nonsignificant between 2-8 mm contrast, 9-17 mm contrast and 2-17 mm contrast.
hhen the preference for larger prey is expressed as the percentage of total reference shown for small and large prey offered to the fishes in all size contrast groups, the following results were obtained.

| Fish size | 50 | 80 | 90 | 110 | 120 | 135 | 155 | 170 |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| \% preference for larger prey | 40 | 57 | 54 | 78 | 73 | 73 | 82 | 87 |

For each of the 5 fishes (total length $110-170 \mathrm{~mm}$ ) where the largest musid size offered ( 27 mm ) was within the limits of
preferred size range (Fig 28) the percentage preference for larger prey was above $70 \%$.

Summary and Conclusions
The results of ecological work on the diet of $P$. gunnellus suggested the possibility of some prey size selection by the fish and the laboratory observations with stationary prey supportod this view.

Fishes of different sizes were not found to show proference for a prey of a particular size; instead a wide prey size range existed for which the fish showed higher preference. Por example a fish of 17.0 cm did attack stationary prey of up to 60 mm , but it showed preference for a size range of 12-35 mm.

The width of the preferred size range increased with increasing fish size which was mainly due to the increase in the upper limit of the size range. (fis 28 ). The lower limit of the preferred size range wes found to be similar between 110-170 mn fishes.

The results did not indicate any difference between first and successive presentations, i.e., the preference shown for a prey sige range did not alter markedly with hunger level as it did in
S. spinachia.

When the variation of preference for smaller or larger prey was examined with respect to the difference in prey size, it was found that in those fishes where the unper limits of the prey size range offered was within the preferred size range, the fishes more often selected the larger prey first in all size contrast groups except 2 mm . Also, 4 Iishes out of five showed an increasing preference for larger prey until the contrast between small and large prey reached 8 mm , after 8 mm contrast it remained unchanged.

From these results it can be concluded that there is a selection of prey sizes in $P$. gunnellus when all sizes are equally catchable but this selection is not as well defined as in $\mathrm{S}_{\text {. spinachia. }}$ There exists a wide preferred size range which increases with fish size. The fish is, however, not completely indiscriminate within its preferred range and the larger of the two preys offered is selected.

In the laboratory, the size of prey selected by P. qunnellus. within wide limits, dops not seem to depend on the actual size.of the prey but is based more upon the fishes ability to discriminate between large and small prey. This would imply that aize selection
observed in the field must be partly a result of fishes ability to capture prey rather than an instinctive selection for size.

THE EFFECT OP MOVENENT ON THE FEEDING RESPONSES OF P. GUNNELLUS.

Cbservations on the general feeding behaviour of P . gunnellus in the laboratory showed that the fish readily took both moving and stationary prey if given separately; if given together the fish seemed to respond more to moving prey, though attempts to capture fast swimming prey were not always successful. Such observations suggested that moving prey might induce a stronger response than stationary prey. The following experiments were carried out to determine whether or not the preference shown for moving prey was significantly different from that shown for stationary prey.

Once again mysids were used as prey. The epparatus used was the same as that described for S. spinachia except that only one moving and one stationary prey were offered to the fishes at each presentation.

Six fishes ranging in total length from 90 to 170 man were used in these experiments, the results were later combined.

The size of moving and stationary prey were kept equal throughout the experiments. The following, prey size ranges were used for each fish. All prey used were within the preferred size range of the fishes.

| Fish size (cm) | 9.0 | 11.0 | 12.0 | 13.5 | 15.5 | 17.0 |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
| Prey size (mm) | $12-14$ | $12-14$ | $12-14$ | $14-16$ | $14-16$ | $14-16$ |

There was also the possibility that the effect of movement on feeding was stronger at certain speeds than others. It was therefore necessary to test the feeding responses to prey at different speeds. Five speeds, varying between $0.2 \mathrm{~cm} / \mathrm{sec}$ to $3.9 \mathrm{~cm} / \mathrm{sec}$ were used.

At each presentation one moving and one stationary prey of equal size were offered to the fish and the number of times it first responded to each one (i.e., either attacked, bit off a portion or swallowed) were recorded. Table 84 gives the results of the preference shown for moving and stationary prey at different speeds. The difference in the number of responses shown to each state of prey was tested by the $\boldsymbol{X}^{2}$ test. (See also Fig. 31).

The $\chi^{2}$ values show that when the prey was moving very slowly,

$$

Fig. 31. P. gunnellus. The relationship between the percentage preference for moving prey and the apeed of the prey.

at a speed of $0.2 \mathrm{~cm} / \mathrm{sec}$, the number of attacks to moving prey did not differ significantly from those made to stationary prey. When the speed of prey increased to $1 \mathrm{~cm} / \mathrm{sec}$, the responses shown to moving prey suddenly increased. The difference in the number of attacns to moving and stationary prey was significant at p<0.001.

As the speed of prey increased further to $1.9 \mathrm{~cm} / \mathrm{sec}$ and 2.9 $\mathrm{cm} / \mathrm{sec}$ the fishes continued to show preference for moving prey and the $X^{2}$ values, which measure the difference between the number of responses shown to each state, continued to increase. When the speed of moving prey reached $3.9 \mathrm{~cm} / \mathrm{sec}$ the number of attacks to moving prey dropped drastically; although the number of attacks to moving prey were still higher than those made to stationary prey the difference did not reach a significant level.

The results of the comparisons of the responses shown to stationary and moving prey between different speeds are given in Table85.

The results show the responses recorded at the slowest speed, $0.2 \mathrm{~cm} / \mathrm{sec}$ differ significantly from those observed at $1 \mathrm{~cm} / \mathrm{sec}$, $1.9 \mathrm{~cm} / \mathrm{sec}, 2.9 \mathrm{~cm} / \mathrm{sec}$ but are of the same order as the responses recorded at the speed of $3.9 \mathrm{~cm} / \mathrm{sec}$.

The responses at the speed of $1 \mathrm{~cm} / \mathrm{sec}$ were not significantly different from those at $1.9 \mathrm{~cm} / \mathrm{sec}, 2.9 \mathrm{~cm} / \mathrm{sec}$ but the difference between the responses at $1 \mathrm{~cm} / \mathrm{sec}$ and $3.9 \mathrm{~cm} / \mathrm{sec}$ was found to be significant at the $5 \%$ level. ( $X^{2}$ test).

Similarly there was no difference between the responses observed at $1.9 \mathrm{~cm} / \mathrm{sec}$ and $2.9 \mathrm{~cm} / \mathrm{sec}$ but both were significantly different from those found at $3.9 \mathrm{~cm} / \mathrm{sec}$. The difference between the responses at $3.9 \mathrm{~cm} / \mathrm{sec}$ and lower speeds increased with increasing speed from $1 \mathrm{~cm} / \mathrm{sec}$ to $2.9 \mathrm{~cm} / \mathrm{sec}$.

The nonsignificant $\boldsymbol{x}^{2}$ values found for the comparisons between the speeds of $1 \mathrm{~cm} / \mathrm{sec}$ and $2.9 \mathrm{~cm} / \mathrm{sec}$ indicate that although the preference for moving prey increases from $1 \mathrm{~cm} / \mathrm{sec}$ speed to $2.9 \mathrm{~cm} / \mathrm{sec}$ speed, there is not one optimum speed which evokes the highest response from the fishes.

The results suggest that the speed of $0.2 \mathrm{~cm} / \mathrm{sec}$ is the threshold speed above which the prey is perceived as moving. A high preference is shown for prey moving within the speed range of 1 cm to $2.9 \mathrm{~cm} / \mathrm{sec}$. When the speed of prey reaches to $3.9 \mathrm{~cm} / \mathrm{sec}$ it becomes much too fast for the fish to follow and attack the prey and the preference for movement is reduced to the level found at $0.2 \mathrm{~cm} / \mathrm{sec}$.

The effect of novement on the feeding sequence at a low hunger level.
The next set of observations were made to test whether the movement of prey could produce feeding responses when the satiation level of the fishes was high.

The fishes were first fed on stationary mysids attached singly to a tube on the movable arm of the motor which could later be moved at a known speed. The size of the mysids offered in each presentation were once again kept constant.

When the fishes were hungry they responded to prey almost impediately, attacking, biting parts of the prey off or swallowing it completely. As the hunger level dropped the attacks and swallows did not occur as readily. If an attack or swallow did not take place within a minute, the stage of feeding was recorded which was either fixate or fixate + approach.

The same prey was then moved with a soed of $1.9 \mathrm{~cm} / \mathrm{sec}$ by switching on the motor and whether or not any changes in feeding stages occurred werc noted. Positive changes were those that took place from an earlier stage to a later stage in the feeding sequence.

If feeding responses shown to stationary prey stopped at the fixate stage, the possibilities of positive changes were from
a) Pixate to fixate + fpproach
b) Pixate to fixate + approach + attack
c) Fixate to fixate + approach + ettack + swallow (wholly or partially).

If the feeding had stopped at the approach stage, the positive chenges that could occur were
d) From approach to approach + attack
e) From approach to approach +attack + swallow

The number of times the changes a-e occurred were recorded as positive changes.

No change was recorded when the fishes only fixated or fixated and approached the pre $\because$ in both stationary and moving states without showing any further resjonses.

The only possibility of negative responses were from approach to fixate stage i.e., when the fish approached the stationary prey but observed it without following when it began to move.

If a high degree of motivation vas produced by the movement of prey, one would expect the number of positive changes to differ sigaificantly from the number of no changes and number of negative changes. If the feeding motivation produced by moving and stationary prey were not different, the difference between the three categories should not reach significant levels.

Table 86 gives the number of positive, negative and no changes observed in these experiments.

The total number of positive changes were found to be significantly higher than no changes, negative changes and the sum of the two when compared by a $\chi^{2}$ test. $X^{2}$ values for these comparisons were $10.25,65.01$ and 4.31 respectively.

Out of 169 observations $58 \%$ were positive changes, $34 \%$ were no changes and $8 \%$ were negative changes.

Among positive changes a higher percentage occurred from the initial feeding stage (fixate) to subsequent (a-c) stages ( $60 \%$ ) than from fixate + approach stages to later stages (d-e) (40\%); the difference being significant at $5 \%$ level. $\left(X^{2}=4.08\right)$.

The lowest number of positive changes were recorded from fixate to fixate + approach stages (change a) which was significantly lower than the number of changes $b$ and $c . X^{2}$ values for the comparisons of a-b and a-c being 4.23 and 5.44 respectively. If the hypothesis that stronger motivation is necessary to induce an attack or swallow than to cause only an approach is accepted, then these results indicate that the movement of prey does indeed provide a strong feeding stimulus. The positive changes $b$ and $c$ or $d$ and $e$ did not differ significantly from one another.

No difference between the no change groups Fixate to fixate or Fixate + approach to Fixate + approach was found $^{\text {. }}$

A control experiment was carried out to test whether feeding responses could be evoked in the absence of food solely by the movenent of the zubes to which the mysids were attached.

After the initial deprivation period, the fishes were first shown the stationary glass tubes and any responses shown to them within 2 mins were recorded. The tubes were then moved with a speed of $1.9 \mathrm{~cm} / \mathrm{sec}$ and the number of positive changes, no changes and negative changes were recorded.

Table 87 shows the number and type of changes observed by the movement of zubes alone. Out of 121 observations, $39 \%$ were positive changes, $56 \%$ were no changes and $5 \%$ were negative changes. The number of movements induced by movement vere significantly lower than number of no changes $\left(X^{2}=3.84 \quad p=0.05\right)$ and from sum of no changes and negative changes ( $X^{2}=6.03 \mathrm{p}<0.02$ ).

Among the positive changes the percentage of changes from fixate to fixate + approach were highest (70; ). The changes from fixate to Fixate + approach were significantly higher than changes from Fixate to fixate + approach + attack. $\left(X^{2}=11.9\right.$ $p$ © 0.001 ). This was a reverse situation to that found among
positive chenges induced by moving prey. (Table 86 , column $a, b$ ) which meant that although the fish do respond to the movement of the tubes alone, movement plus prey provides a stronger feeding motivation than morement of the tubes by themselves.

The highest number of no changes occurred at Fixate to fixate stages (54\%). The number of negative changes were very low.

The effect of movement on selection of larger prey
One of the conclusions of the prey size selection experiments in F. gunnellus was that the fish showed preference for the larger of the two oreys offered within its preferred size range and that this preference was independent of the fishes preferred size range. For example, if the preferred prey size range of a fish was 10 to 20 mm and if it could detect a difference of 5 m rrcy size, when offered preys of 10 and 15 mm , it would select the 15 nm prey. If, however, it was offered preys of 15 and 20 mm lengih, it would select the 20 mm prey.

Experiments with moving and stationary prey showed that the preference for moving prey wis very high. The next set of observations were made to compare the effects of movement on prey contrast selection.

Two fishes of 15.5 cm and 17 cm were used. At each presentation one large (20 rm) and one small (12 m) mysid, both stationary, were offered to the fishes and the number of times small and large prey were selected were resorded. The size of the mysids vere within the preferred size range of fishes (see above).

In a second set of observations the large gysid was kept stationary and the small mysid was moved with the speed of $1.9 \mathrm{~cm} / \mathrm{sec}$, noting the number of times each one sas selected. The sizes of mysids ware the same as before.

Table 88 gives the percentage preference for larger prey when both were stationary and when the small prey was moving for each fish.

When both large and small prey were stationary (Group A) the preference for large prey was above $80 \%$ for eeci fish.

The number of small and large prey selected did not differ significantly between the two fishes. $\left(\boldsymbol{x}^{2}=0.31 \mathrm{p}>0.10\right)$.

When the large prey was stationary and the saall prey was moving (Group B) the preference for larger prey to less than $50 \%$ in both fishes.

The comparison of the number of large and syall prey taken
between Group A and B were significantly different for fach fish at $\mathrm{p}<0.001$. The $\boldsymbol{X}^{2}$ values were 11.46 for the 15.5 cm Pish and 23.6 for the 17 cm fish.

The results suggested that movement of the prey overrules :ie effect of size.

## Sumary and Conclusions

Observations with moving and stationary prey indicated that moring prey was selected in preference to stationary prey. By testing the responses to morement at varying speeds between $0.2 \mathrm{~cm} / \mathrm{sec}-3.9 \mathrm{~cm} / \mathrm{sec}$ it was found that the effect of movement in producing responses varied with the speed of prey within these limits. The thresholà speed was found to be $0.2 \mathrm{~cm} / \mathrm{sec}$, above which the movement of prey evoked significantly higher number of responses. The preference for movement increased slightly between $0.2 \mathrm{~cm} / \mathrm{sec}$ to $2.9 \mathrm{~cm} / \mathrm{sec}$ but the increase was not found statistically significant. The preference decreased meracdly above $2.9 \mathrm{~cm} / \mathrm{sec}$ (Iebles $84 \& 85$ which suggested that the optimal speed of prey was between $1 \mathrm{~cm} / \mathrm{sec}$ to $2.9 \mathrm{~cm} / \mathrm{sec}$.

A set of observations which examined the type and number of changes indiced by movement of prey showed that even at a high

## satiation level =orement brought about a significantly higher number of changes. (Iable 86 ). <br> A control experiment tested whether the movement of tubes normally used to hold prey could evoke feeding responses when the fishes were bungry i.e., when they were most responsive. It was found that tube zovement alone could still induce a number of feeding responses which mainly consisted of following the tubes. The number of times the positive responses occurred were significantly less than incidents of no responses. <br> When two stationary prey, large and small were offered to the fishes, a high prefierence for the larger prey was found. (Table 88. Group A). If the small prey began to move the preference shown for large prey no longer existed which suggested that movement decreases the effect of the size stimulus. <br> Prom all these results it can be concluded that the movement is an important stimulus for feeding in P. quanellus. <br> COMPARISON OF TEE FEEDING BEHAVIOUR OF S. SPINACHLA AND P. GUNNELLUS

Both S. spizachia and P. gunnellus were found to show prey size selection unier experimental conditions. The pattern of
selection was, however, different in the two species.
When S. spinachia were offered prey of different sizes, most fish were found to select prey within a preferred size range, above and below which the fish tended to reject the offered prey. Selection became progressively more pronounced as the hunger level of the fish dropped. P. gunnellus on the other hand, responded to prey with a wider size range in all fish size groups examined and no clear indication of increasing selectivity with decreasing hunger was found. The fish still continued to attack prey sizes much outside their preferred size range, whereas in S. spinachia the number of positive responses to prey outside its preferred size range were considerably reduced at higher satiation levels.

The differences in the prey size range for the two species may be demonstrated by calculating the ratio of fish size to preferred prey size range. Table 89 shows these ratios for 10 S. spinachia and 8 P. gunnellus.

The table shows that the $\frac{\mathrm{FS}}{\mathrm{PR}}$ ratio was relatively constant in both species. The mean $\frac{F S}{P R}$ ratio was 10.98 for S. spinachia: and 7.56 for $P$. gunnellus. It is thus clear that $P$. gunnellus prefers a wider size range than S. spinachia.

Iz6! 28 . The ratio of $\frac{\text { fish size }}{\text { preferred prey size range }}\left(\frac{\mathrm{FS}}{\mathrm{PR}}\right.$ ) for S. spinachia and P. gunnellus.

Furthermore, in S. spinachia an optimal prey size was foumd within the preferred size range for which the highest preferense wis shown. In $P$. gunnellus the preference shown for different size groups within the preferred size range did not differ markedly and no optimal prey size was apparent. The observations suggested tiot ?. zunnellus selected the larger of the two preys offerred within :2e jeierred size range regardless of their absolute size.

Such results implied that prey size selection demonstrated by 3. spinachia under experimental conditions is more specific then that of $P$. gunnellug. It is possible that the observed differences
in prey size selection may be a result of morphological differences in tine shape and/or size of mouth and teeth between the two species. It has been mentioned earlier in the section describing the general feeding behaviour of $S$. spinachia that the fish took تysids whole and that biting off only a portion was rare. In $P_{\text {. gunnellus on }}$ the other hand, although the fish did usually swallow prey whole, biting parts off the prey body was much more frequent. It was considered that this biting habit might be related to the anatomy of the mouth and dentition. To elusidate this question, the mouth size (gape) and teeth of the $t=0$ species were examined in more detail.

The mouth size measurements of S. spinachia were given earlier in Fig 22. The mouth size of P. gunnellus was measured similarly, by insering graduated drills of known size into the fishes mouth. 35 Ireshly killed fish with a size range of 59-156 mm were used for these measurements. The relationship between the mouth diageter and the total length of P. gunnellus is given in Fig 32, Line A. For comparative pusposes, the regression line stowing the relationship between mouth size and fish size of $S . \operatorname{szinachia}$ is also given on the same figure (Line B).

Fig32 shows inat for a given length the mouth size of

FISH SIZE (CM)
Fig. 32. P. gunnellus. The relationship between total length and mouth diameter (Line A). Line $B$ is the regression line for the relationship in Spinachia and is included for comparison,
P. gunnellus is slightly larger than thet of S. soinachia. Also the arrangement and the shape of teeth differ between the two species, the teeth of P. gunnellus being more pointed than those of S. spinachia. (Pig33). The observed behavioural differences might be therefore due to t上e Eifferences in mouth size and teeth shape.

Both fish showed a distinct prefereace for moving prey over stationary prey. There was a thresiold speed ( $0.2 \mathrm{~cm} / \mathrm{sec}$ ) above which moving prey were chosen in greference to stationary prey by both fishes. They both responded to prey moving with a speed between $1 \mathrm{~cm} / \mathrm{sec}$ to $2.9 \mathrm{~cm} / \mathrm{sec}$. The preference for moving prey was highest at $2.9 \mathrm{~cm} / \mathrm{sec}$ in S. spinachia; in P. gunnellus no similar optimal speed was apparent within the $1 \mathrm{~cm} / \mathrm{sec}-2.9 \mathrm{~cm} / \mathrm{sec}$ speed range. Above $2.9 \mathrm{~cm} / \mathrm{sec}$ the number of responses of P. gunnellus to moving prey decreased markedly. In S. spinachia there was a slight decrease, but preference for movement still remained at a high level at the next speed tested, $3.9 \mathrm{~cm} / \mathrm{sec}$. It is concluded therefore, that P. gunnellus prefers a narrower speed range, the upper limit of which is lower than. that of S. spinachia. This difference may be related to the fact that S. spinachia can swim faster than E. Finnellus. Blaxter \&

Jicison（1958）give a maximum speed of $72 \mathrm{~cm} / \mathrm{sec}$ for
3．$E$＝iachetia and $30 \mathrm{~cm} / \mathrm{sec}$ for $P$ ．gunnellus．
In both species movement of the prey produced sufficiently sirong aotivation to induce further feeding at relatively嫁 satiation levels．The tyo and the number of feeding ＝ミミロロnsis evoked by the movement of prey were similar in both species．

The results of the comparisons of size and movement stimuli for both fish were also similar．In S．spinachia moving prey were iaken in preference to optimal sized prey，but the size cue from ：$:$ g prey was not completely ignored．In P．gunnellus the E＝ffereace for larger prey disappeared when the small prey was ＝oviag and the large prey was siationary．For both fishes， ：he：efore，movement was the stronger stimulus of the two．
$\overline{\text { rizally，}}$ ，it must be considered how much the feeding ecology of the tho species can be explained by the results of the observations on their feeding behaviour．In the field， 3．Bjirachia was found to show a size related feeding heterogeneity． Obserrations in the laboratory with stationary mysids suggested ：Ee：groy size selection had e bahavioural brsis；therefore， ： E ：Eirision of different prey emong different fishsize groups founc in the field must have been，at least partly，a result of
fishes behaviour $\mathfrak{z e} \pm t e r n$ and not entirely due to prey availability or caichzoility. In P. gunnellus the relationship between the fish size and prey size in the .Pield was not as marked as that foum in S. spinachia. These results were supported by the $I \equiv$ ミorp:ory experiments where $P$. gunnellus showed a less well Exined size selection.

The observa:i:2s in the laboratory on both p. punnellus and S. spinachia further indicated that the preferred prey size range increased wizh increasing fish size and this was paralleled in the field, where, as in the laboratory, the increase in the prev size range wes due mainly to an increase in the upper limit of top preferred $\because=2$ size range. The lower limit of preferred

Both S. spicachie end P. gunnellus attacked the head of the prey in prefesenes to the rest of the body. This seems to be a common feature of predatory behaviour but may account for the presence of decapod heads in P. gunnellus stonachs. S. spinachia. as has already been mentioned, tended to swallow its prey whole. Apart from the dififrences in wouth size already referred to, mouth shape may $e!\leqslant 0 \quad \delta \in$ important in this respect. S. spinachia's mouth is long and :ibular whereas that of $P$. gunnellus is shorter
and jaw muscles appear to be much more powerful.
In the laboratory it was observed that $P$. gunnellus took food most easily from the botton although it could also take it from the surface. S. spinachia on the other hand could take food easily from all levels of water. Differences in diet between the two species may therefore also be attributatie in some measure to their swimming habits and mode of life. P. gunnellus is negatively buoyant and almost entirely restricted to the bottom whereas S. spinachia is neutrally buoyant and cen swin at any level with ease. For example, planktonic copepods were commoner in the diet of S. spinachia than in that of P. zungellus where those copepods present consisted almost entirely of bottom living harpacticoids. Similarly, polychaetes were an imporant part of the diet in P. gunnellus but were rarely taken by S. spinachia.

As mentioned earlier, P. gunnellus was found to have a lower preferred prey speed range than S. spinachia. Some differences in the diet of the two species in the field might be a rosult of the fact that $P$. gunnellus prefers slower moving orey than S. spinachia. The speeds of movement of the various prey organisms in the field are not known; but although sedentary
molluscs suci as gastropods and bivalves were not very significan: $\vdots=$ ine diet of either species, they occurred more frequenil: in $P$. gunnellus. This could be influenced by the speed preferences of the fishes.

They $5= \pm \equiv 1$ so indications from the laboratory observations that S. soine: ie =xhibited shape and contrast discrimination; but it is not possible to infer to what extent these factors influence prey selection in the field. Comparable experiments were not carried out vish $P$. gunnellus.

Althouż :he effects on food selection of only a few visual cues were $\sum_{\text {Eresicigated }}$ in this work, some may be used to explain the natural $\tilde{i}_{\epsilon}=\mathrm{ding}$ behaviour in general terms. Nevertheless, it would $b \in i=$ oressimplification to say that a complete interpretation of the field results is possible on the basis of few visual sitarli tested. A more detailed analysis of the fishes diet to deternine the degree of preference shown for different food species as vell 25 sone measures of abundance and distribution of prey species in the sea would be required. Also, further laboratory =ksfracions on the rate of learning, taste discrimination and experi=E: 5 -i i h models of different shapes and colours would be necessa:-: $: \operatorname{gain}$ a complete insight into the extent which the fishes behericur determines the selection of its prey in the field.

[^2]:    * See Appendix

[^3]:    *See Appendix

[^4]:    * See Appendix

[^5]:    In the field vith free swimming prey, the cost of obtaining prey will consist of the energy expanded in searching and pursuit i.e., the time required for the predator to find and capture the prey, together with handling time, defined as the time required to swallow the captured prey.

    Pig 25 shows that below a critical size all prey size groups had approximately the same handling tire (5 secs). Thus it will be most beneficial for the fish to swallow the largest prey nearest to and below this critical size, thereby maximising the cost/benefit ratio. If this assumption is correct then one would expect that the optimal prey size for the fish, as estimated from the previous experiments, should lie close to the critical size after which handling time begins to increase rapidly. As explained earlier, the critical size was taken as the point at which handling time became consistently 8 secs, as it was in this region that handling time began to increase in 3 out of 4 cases illustrated in Fig 25. Comparisons of the estimates of critical size for each case in Fig. 25 with the estimsted optimum size are shown in Table 81.
